ABSTRACT

We present model spectral energy distributions (SEDs), colors, polarization, and images for an evolutionary sequence of a low-mass protostar from the early collapse stage (Class 0) to the remnant disk stage (Class III). We find a substantial overlap in colors and SEDs between protostars embedded in envelopes (Class 0–I) and T Tauri disks (Class II), especially at mid-IR wavelengths. Edge-on Class I–II sources show double-peaked SEDs, with a short-wavelength hump due to scattered light and a long-wavelength hump due to thermal emission. These are the bluest sources in mid-IR color-color diagrams. Since Class 0 and I sources are diffuse, the size of the aperture over which fluxes are integrated has a substantial effect on the computed colors, with larger aperture results showing significantly bluer colors. Viewed through large apertures, the Class 0 colors fall in the same regions of mid-IR color-color diagrams as Class I sources and are even bluer than Class II–III sources in some colors. It is important to take this into account when comparing color-color diagrams of star formation regions at different distances or different sets of observations of the same region. However, the near-IR polarization of the Class 0 sources is much higher than the Class I–II sources, providing a means to separate these evolutionary states. We varied the grain properties in the circumstellar envelope, allowing for larger grains in the disk midplane and smaller grains in the envelope. In comparing with models with the same grain properties throughout, we find that the SED of the Class 0 source is sensitive to the grain properties of the envelope only—that is, grain growth in the disk in Class 0 sources cannot be detected from the SED. Grain growth in disks of Class I sources can be detected at wavelengths greater than 100 μm. Our image calculations predict that the diffuse emission from edge-on Class I and II sources should be detectable in the mid-IR with the *Space Infrared Telescope Facility* (*SIRTF*) in nearby star-forming regions (out to several hundred parsecs).

Subject headings: circumstellar matter — dust, extinction — polarization — radiative transfer — stars: formation — stars: pre–main-sequence

1. INTRODUCTION

Low-mass protostars have been grouped into an evolutionary sequence, Class 0–Class III, on the basis of their spectral energy distributions (Lada & Wilking 1984; Lada 1987; Myers et al. 1987; Strom et al. 1989; Adams, Lada, & Shu 1987; André, Ward-Thompson, & Barsony 1993). Class 0 sources are in the early protostellar collapse stage, with spectral energy distributions (SEDs) that resemble blackbodies with $T \leq 30$ K (André et al. 1993). The majority of the source mass resides in the infalling envelope. Even at this early stage of collapse (of order a few times 10^4 yr), these sources exhibit powerful, bipolar molecular flows. The Class I stage is a later stage of protostellar collapse that lasts a few times 10^5 yr. These sources display very broad SEDs that peak near 100 μm. Their envelope masses are similar to the mass of the central pre–main-sequence core. They have well-developed accretion disks, and their envelopes have bipolar cavities excavated by outflows (Terebey, Chandler, & André 1993; Kenyon et al. 1993b; Tamura et al. 1991). The Class II stage is characterized by the presence of excess infrared emission above that expected for a stellar photosphere, with the SED emission peak occurring in the near-infrared. This is the signature of a classical T Tauri star surrounded by an accretion disk. Infall from the cloud has ceased owing to dispersal of the remnant infall envelope by the combined effects of infall and outflow. Class II sources have ages of about 10^6–10^7 yr (Strom et al. 1989). The Class III sources, also known as "weak-lined" T Tauri stars, have SEDs that resemble a stellar photosphere. Mid-IR radiation from remnant disk material, if it exists, should be detectable by the upcoming *Space Infrared Telescope Facility* (*SIRTF*). It is not known for certain whether Class III sources are more evolved than the Class II sources or whether they have simply lost most of their circumstellar material on a faster timescale. The Class III stage can last for about 10^7 yr, ending in a zero-age main-sequence star (Palla 1999).

Interpretations of the SEDs of pre–main-sequence stars have traditionally relied on one- or 1.5-dimensional radiative transfer models of spherical envelopes for Class 0–I sources (Adams et al. 1987; Kenyon, Calvet, & Hartmann 1993a; Jayawardhana, Hartmann, & Calvet 2001) and flat or flared-disk models for Class II sources (Kenyon & Hartmann 1987; Chiang & Goldreich 1997; D'Alessio et al. 1998, 1999; Dullemond, Dominik, & Natta 2001; Dullemond 2002; Dullemond & Natta 2003). While the Class II models do a good job matching observations of pure disk sources, the models for younger sources generally do not take into account bipolar cavities created by outflows, vertically extended disks in Class 0–I sources, inclination effects, or intermediate stages between Class I

(envelopes) and II (disks) sources. These models appeared sufficient to explain the previously sparsely sampled SEDs, although it was clear early on that they failed to account for the large optical/near-IR flux from most Class I sources (Adams et al. 1987). Kenyon et al. (1993b) showed that bipolar cavities allow a sufficient amount of near-IR flux to scatter out to match the observations. Now with more complete SED information on several sources showing more complicated SEDs (Liu et al. 1996; Chandler, Barsony, & Moore 1998; Rebull et al. 2003; Wolf, Padgett, & Stapelfeldt 2003), and with the upcoming *SIRTF* mission, which will sample more frequencies in the mid-IR, it is clear that two- and three-dimensional models are required to interpret these sources.

In a previous paper (Whitney et al. 2003, hereafter Paper I), we showed that including a flared disk and a bipolar cavity in models of Class I sources leads to more complicated SEDs than those from one- or two-dimensional models with rotationally flattened envelopes only (Efstathiou & Rowan-Robinson 1991). We showed that the near- and mid-IR colors of two-dimensional models are substantially bluer than those from one-dimensional models for a given envelope mass. Thus, using one-dimensional models to interpret sources that are not spherical will lead to an underestimate of the mass of the envelope and an overestimate of the evolutionary state.

This paper follows up Paper I with models comprising an evolutionary sequence from Class 0 to Class III. Our goal is to provide more accurate interpretations of observations. We find substantial overlap between colors of sources at different evolutionary stages in the mid-IR wavelengths that *SIRTF* will observe. The information provided by SEDs alone may not be sufficient to interpret a source's evolutionary state, since, for example, a more pole-on Class I source can resemble an edge-on Class II source. Combining more information from images and polarization, which help determine inclination and size, can resolve this degeneracy. Section 2 of this paper describes the models, § 3 describes the resulting SEDs, colors, images, and polarization spectra, and § 4 summarizes the results.

2. MODELS

2.1. *Circumstellar Geometry*

For the infalling envelopes, we use the density structure of a rotating envelope in free-fall collapse (Ulrich 1976; eq. [1] of Paper I). The disk density is a flared disk in hydrostatic equilibrium (Shakura & Sunyaev 1973; Pringle 1981; eq. [3] of Paper I). The envelopes have curved bipolar cavities filled with constant density gas and dust. The cavity shape follows $z = a\varpi^b$, where $\varpi = (x^2 + y^2)^{1/2}$ is the cylindrical radius.

We computed six models comprising an evolutionary sequence from Class 0 to Class III. This evolutionary sequence is characterized by a decreasing envelope infall rate, increasing disk radius, increasing bipolar cavity opening angle, and decreasing cavity density. The density structures for each model are shown in the right panels of Figure 3. For more detailed plots of the disk/envelope density in the inner regions, see Figure 2 of Paper I. Table 1 shows the parameters common to all models. The stellar parameters are typical of a low-mass T Tauri star. The disk parameters are based on models of T Tauri disks in hydrostatic equilibrium (D'Alessio et al. 1998) and models of observed images (Cotera et al. 2001; Wood et al. 2002b). The disk density is proportional to $\varpi^{-\alpha}$. The disk scale height increases with radius as ϖ^{β} scaled to the value of h_0 at the stellar radius, given in Table 1. The disk viscosity parameter, $\alpha_{\rm disk}$, is taken from models of average passive T Tauri accretion disks (D'Alessio et al. 1999), based on the α-disk prescription (Shakura & Sunyaev 1973; Kenyon & Hartmann 1987; Bjorkman 1997; Hartmann 1998; see eqs. [5] and [6] of Paper I). This is used in our calculation of disk accretion rate and luminosity (Table 2).

TABLE 1
COMMON MODEL PARAMETERS

Parameter	Description	Value
R_* ($R_\odot$)	Stellar radius	2.09
T_* (K)	Stellar temperature	4000
M_* ($M_\odot$)	Stellar mass	0.5
L ($L_\odot$)	Source luminosity	1
α	Disk radial density exponent	2.25
β	Disk scale height exponent	1.25
h_0	Disk scale height at R_*	0.01
$\alpha_{\rm disk}$	Disk viscosity parameter	0.01

Table 2 shows the parameters that vary among the six models. The envelope infall rates are based on previous models of Class 0 and I sources (Adams et al. 1987; Kenyon et al. 1993a, 1983b; Jayawardhana et al. 2001; Stark et al. 2003). The envelope mass is determined by a combination of several parameters: envelope infall rate, centrifugal radius (=disk outer radius), outer envelope radius, cavity size, shape, and density. In the models with infalling envelopes (Class 0–I), the envelope mass grows with radius as $r^{1.5}$. Thus, the envelope mass tabulated is only that within 5000 AU, our chosen outer envelope radius. The envelope inner radius and disk inner radius are chosen to be at or slightly larger than the dust destruction radius (except for the Class III source); this is larger in the more dense disks. The Class III disk inner radius is chosen to be 50 stellar radii since evolved disks can have large inner holes (e.g., HR 4796; Koerner et al. 1998). The disk mass is chosen to be 0.01 $M_\odot$ for all evolutionary states except Class III. This mass is typical for Class 0–II sources (Beckwith et al. 1990, Terebey et al. 1993; D'Alessio, Calvet, & Hartmann 2001; Looney, Mundy, & Welch 2003). The disk size is expected to grow with time for envelopes that initially rotated as a solid body. Our choices of disk size are based on previous modeling and observations (Beckwith et al. 1990; Kenyon et al. 1993a, 1993b; Stark et al. 2003; Padgett et al. 1999). The envelope centrifugal radius is chosen to be the same as the disk outer radius. The disk accretion rate and contribution to luminosity varies between the models because of different disk densities. We note that its effect on the SEDs and images is small. The Class III disk mass is chosen to be 10^{-6} $M_\odot$. For more complete treatments of Class III disks and debris disks exploring a wider range of parameter space in mass and dust properties, see Wood et al. (2002a) and Wolf & Hillenbrand (2003). The bipolar cavity densities are based on observations of molecular outflow densities (Moriarty-Schieven et al. 1992, 1995a, 1995b) and our assumption that these would decrease with evolution. The cavity opening angles are also expected to increase with age, and our choices are based on images of molecular outflows and envelopes (Chandler et al. 1996; Tamura et al. 1996;

TABLE 2
MODEL VARIATIONS

Class	0	Late 0	I	Late I	II	III
Envelope infall rate ($M_\odot$ yr^{-1})	1×10^{-4}	1×10^{-5}	5×10^{-6}	1×10^{-6}	0	0
Envelope mass ($M_\odot$)	3.73	0.37	0.19	0.037	1×10^{-4}	2×10^{-5}
Envelope inner radius (R_*)	7.5	7.5	7	7	7	50
Envelope outer radius (AU)	5000	5000	5000	5000	500	500
Disk mass ($M_\odot$)	0.01	0.01	0.01	0.01	0.01	2×10^{-8}
Disk inner radius (R_*)	7.5	7.5	7	7	7	50
Disk outer radius (AU)	10	50	200	300	300	300
Disk accretion rate ($M_\odot$ yr^{-1})	1.4×10^{-7}	2.8×10^{-8}	6.8×10^{-9}	4.6×10^{-9}	4.6×10^{-9}	0
Disk accretion luminosity (L_*)	0.036	0.0069	0.0018	0.0012	0.0012	0
Cavity density (n_{H_2} cm^{-3})	10^5	6.7×10^4	5×10^4	10^4	5×10^3	1×10^3
Cavity opening angle (deg)	5	10	20	30	90	90

Hogerheijde et al. 1998; Padgett et al. 1999) and models of images (Stark et al. 2003). The 90° opening angle for the Class II and III sources is used to give a constant-density envelope at typical molecular cloud ambient densities. The density of the Class III ambient cloud is lower than the other sources since the disk density is low, and it would not be surprising to see Class III sources in less dense regions of the molecular cloud.

2.2. *Radiative Transfer*

The radiative transfer method is the same as described in Paper I. It uses the radiative equilibrium solution method of Bjorkman & Wood (2001) incorporated into a three-dimensional spherical-polar grid. Complicated three-dimensional density distributions can be solved with the same ease as one-dimensional spherical densities. The models properly account for scattering and inclination effects. Most of the source luminosity comes from the central star, with a small amount of accretion luminosity from the disk. The input stellar spectrum is a Kurucz model atmosphere (Kurucz 1994) for the stellar parameters given in Table 1. Both the stellar and disk accretion luminosity are reprocessed by the dusty disk and envelope. An addition to the models in this paper is the capability to include different grains in different regions. A grain model is assigned to each grid cell. Several variables used for the temperature calculation in a cell, e.g., the Rosseland mean opacity, are computed for each grain model used in the calculation.

2.3. *Grain Properties*

Previous modeling of SEDs of disks has shown that to fit images and SEDs of Class II sources (disks) requires large grains with maximum sizes up to 1 mm (D'Alessio et al. 2001; Wood et al. 2002b). On the other hand, to match the colors, images, and polarization maps of Class I sources (mainly envelopes) in the Taurus molecular cloud, grain models similar to the diffuse interstellar medium (ISM) work reasonably well (Kenyon et al. 1993b; Whitney, Kenyon, & Gómez 1997; Lucas & Roche 1997, 1998; Stark et al. 2003; Wolf et al. 2003). For this reason, we allow the grain properties to vary in different regions, as shown in Figure 1. For the dense regions of the disk ($n_{H_2} > 10^8$ cm^{-3}), we use the large-grain model that Wood et al. (2002b) used to fit the HH 30 disk SED. For the less dense regions of the disk, we use the same grain model that Cotera et al. (2001) used to model the HH 30 near-IR scattered light images. These grains are larger than ISM grains, but not as large as the disk midplane grains. For the envelope we use the grain model from Paper I, which has a size distribution that fits an extinction curve typical of the more dense regions of the Taurus molecular cloud, with R_V, the ratio of total-to-selective extinction, equal to 4.3 (Whittet et al. 2001; Cardelli, Clayton, & Mathis 1989). These grains also include a water ice mantle covering 5% of the radius. For the outflow, since small grains can condense in outflows, we use ISM grains that are on average slightly smaller than the envelope grains (Kim, Martin, & Hendry 1994). The grain properties are shown in Figure 2 and are briefly summarized in Table 3. Figure 2 shows that the larger grains (e.g., the disk midplane grains shown by the dashed line) have a flatter opacity, larger albedos (at longer wavelengths), larger g (average cosine scattering angle), and lower polarization (p_l).

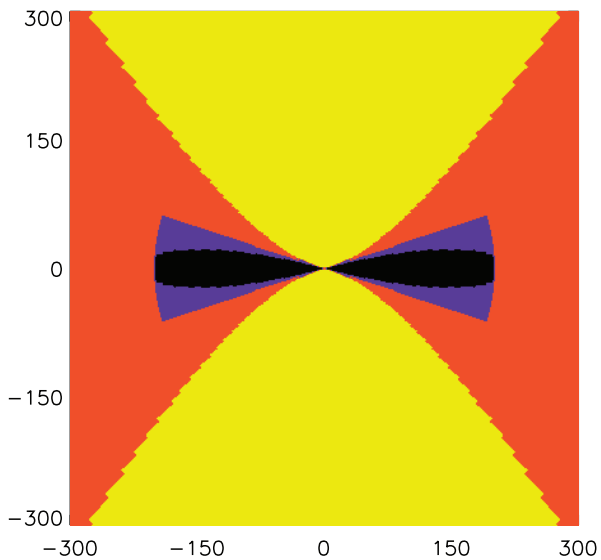

FIG. 1.—Inner region of the grid (300 AU) showing the regions where the different grain models are used. Grid cells colored black have the disk midplane grains (from Wood et al. 2002b), blue cells have the disk atmosphere grains (from Cotera et al. 2001), red cells have the envelope grains (Paper I), and yellow cells have the ouflow grains (ISM grains from Kim, Martin, & Hendry 1994).

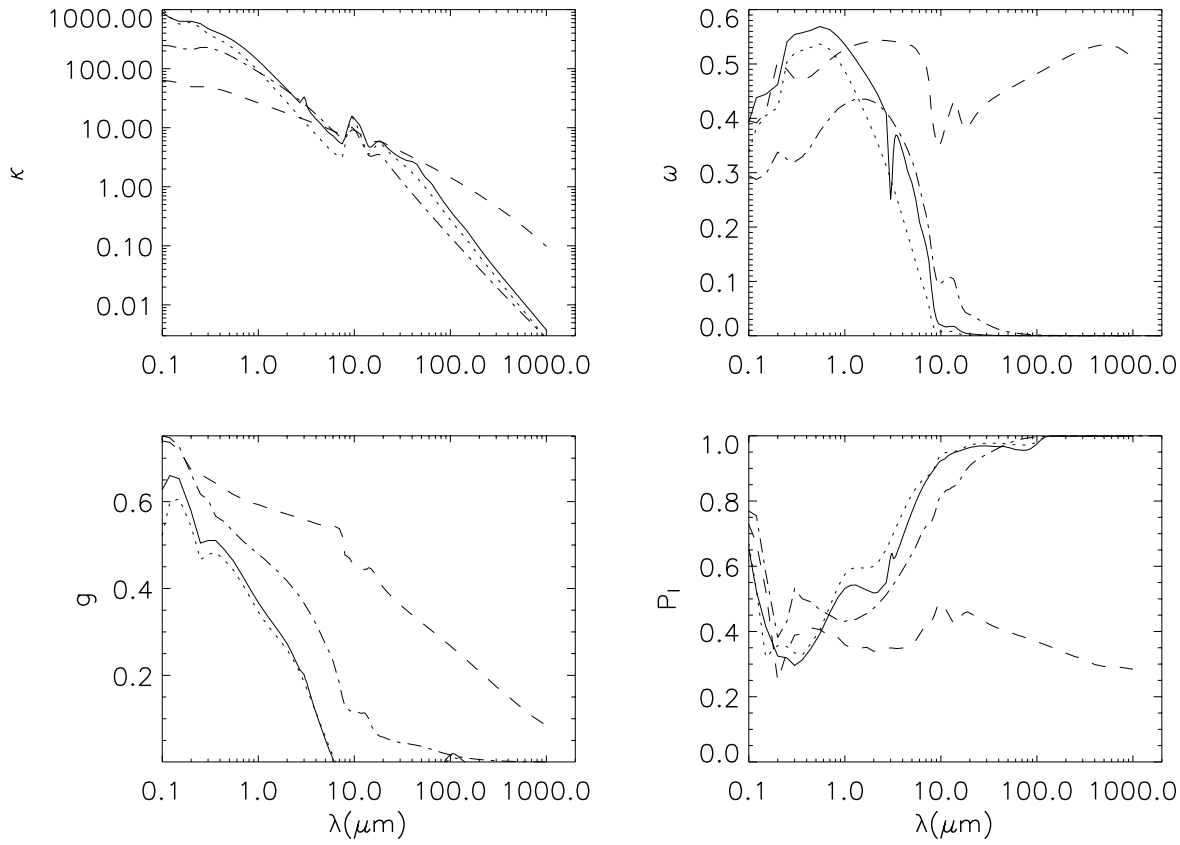

FIG. 2.—Dust properties of the four grain models. Opacity (κ) is shown in the top left panel, albedo (ω) at the top right, average cosine of scattering angle (g) at the bottom left, and maximum polarization P_l typically at 90° scattering angle) at the bottom right. The four lines show the four grain models from Fig. 1 as follows: *solid lines*, envelope; *dotted lines*, outflow; *dashed lines*, midplane disk; *dot-dashed lines*, disk atmosphere .

3. RESULTS

This section displays spectra, colors, polarization spectra, and images for the six evolutionary stages. All of the sources have luminosity $L = 1\ L_\odot$ and are placed at a distance of $d = 140$ pc, for comparison to nearby low-mass star formation regions such as the Taurus molecular cloud.

3.1. *Spectral Energy Distributions*

Figure 3 shows densities and SEDs for the six evolutionary states. The smallest densities displayed (10^{-20} g cm^{-3}) are near the ambient density of $\rho = 1.67 \times 10^{-20}$ g cm^{-3} or $n_{H_2} = 5 \times 10^3$ cm^{-3}. In the inner regions, not shown on the scales plotted here, the densities increase to about 10^{-6} to 10^{-5} g cm^{-3} in the most dense regions of the disk and to about 10^{-11} to 10^{-13} g cm^{-3}, depending on evolutionary state, in the inner envelope. The SEDs in Figure 3 show the emission emergent from the entire envelope. In nearby star formation regions, the flux is often measured in apertures that are smaller than the envelope size. This affects the optical/near-IR flux the most, with smaller apertures giving less flux, as we will show later.

TABLE 3
DUST MODELS

Description	Region	$r_{\rm eff}$	r_V
Disk midplane.....	Inner disk ($n_{H_2} > 10^8$ cm^{-3})	0.69	4.9
Disk atmosphere.....	Upper layers of disk	0.042	4.1
Envelope.....	Infalling envelope	0.048	4.3
Outflow.....	Bipolar cavity	0.026	3.6

For each model, 10 inclinations are plotted, the top and bottom curves corresponding to pole-on and edge-on (*pink and green, respectively*). The largest variations with inclination appear in the mid-IR, with edge-on sources showing a broad dip near 10 μm in the Class I–II sources. The 9.8 μm amorphous silicate feature is much narrower than this. The broad dip is due to two effects: the large extinction in the disk midplane, which blocks thermal radiation from the inner disk+envelope, and the low albedo, which prevents radiation from scattering out the polar regions. The optical extinction, A_V, through the disk midplane is greater than 10^7 in the Class 0 sources and greater than 3×10^5 in the Class I–II sources (see Fig. 3 of Paper I for a plot of A_V vs. inclination angle). Shortward of 10 μm, the Class I and II envelopes allow optical/near-IR radiation to scatter out through the outflow cavities (or upper layers of the disk in the case of the Class II source). Thus the edge-on Class I and II sources are double-peaked, with the short-wavelength peak due to scattering and the long-wavelenth peak due to thermal emission.

The Class II model SEDs are similar to previous models (Kenyon & Hartmann 1987; Chiang & Goldreich 1997; D'Alessio et al. 1998, 1999; Dullemond et al. 2001; Dullemond 2002; Dullemond & Natta 2003) except at nearly edge-on inclinations ($i \gtrsim 70°$), where extinction and scattering dominate at near- and mid-IR wavelengths.

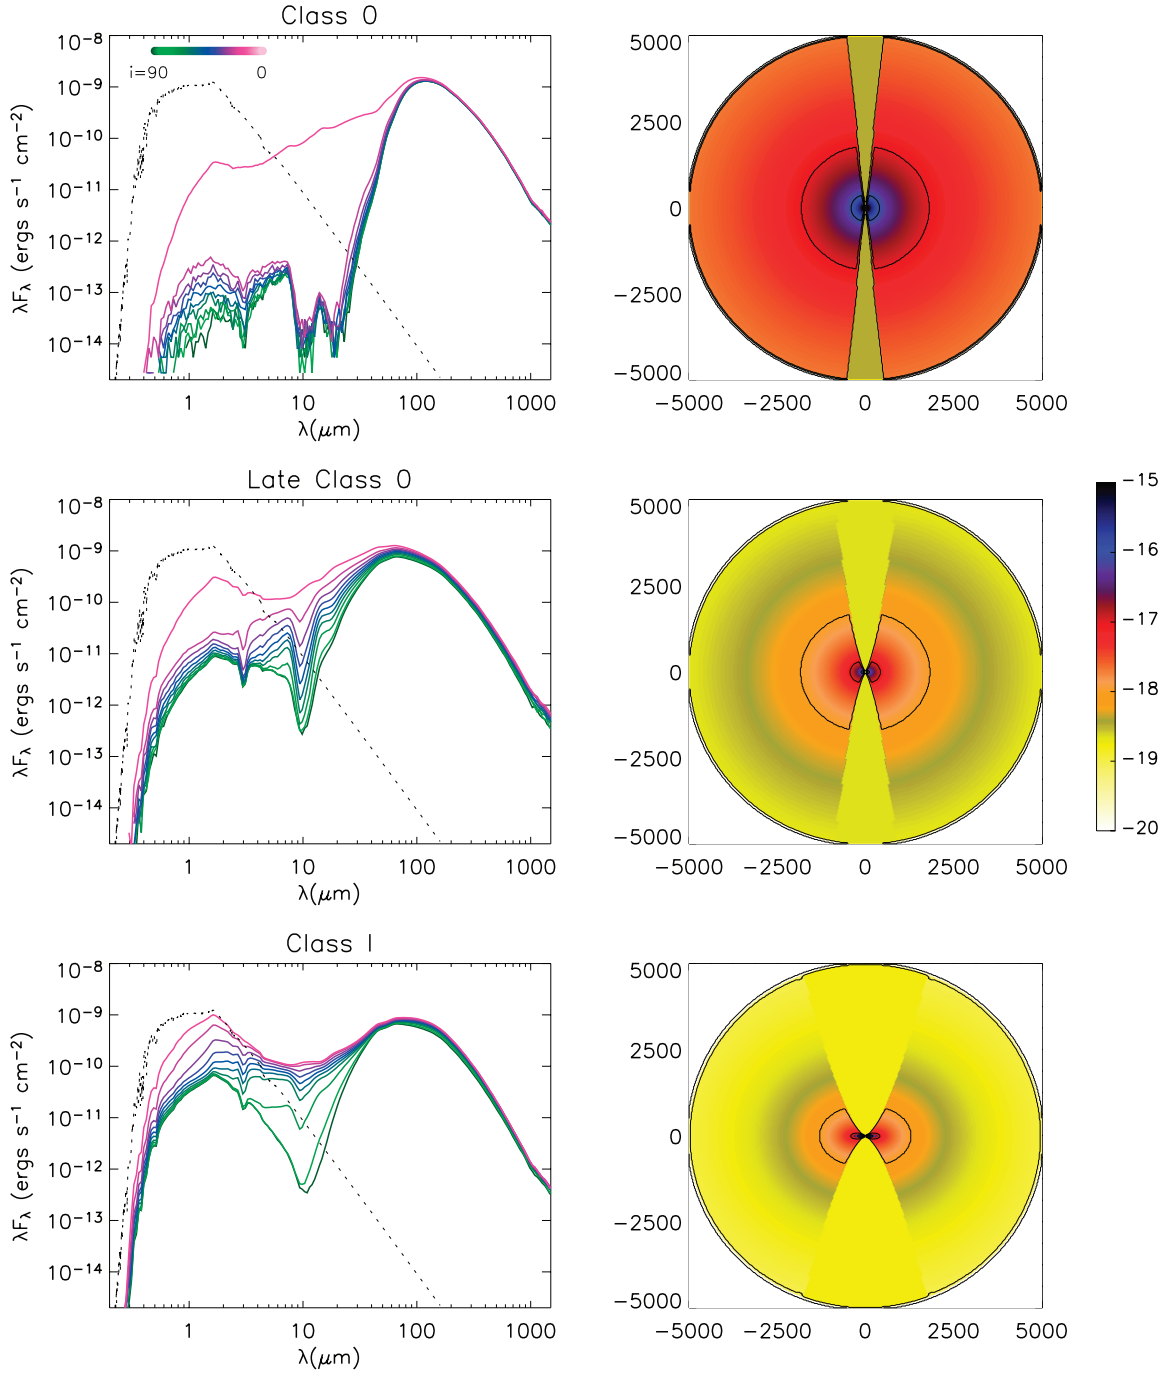

FIG. 3*a*

FIG. 3.—SEDS (*left*) and densities (*right*) of the six models. For the SED models, the colors indicate inclination, as shown in the top left panel: dark green is edge-on, and pink is pole-on. The density images are plotted to log scale, with the contours matching the tick marks in the color bar. The size range is noted in the axes in AU. Note that the Class II and III sources (disks) are much smaller than the envelope sources. (*a*) Class 0, late Class 0, and Class I. (*b*) Late Class I, Class II, and Class III.

D'Alessio et al. (1999) include these effects, and their models show behavior with inclination similar to ours. Dullemond (2002) calculated the two-dimensional structure of disks and Herbig Ae/Be stars and found that the inner wall puffs up and shadows outer regions in these sources. Since we do not compute the two-dimensional hydrostatic equilibrium solution, we do not have this effect in our models. A forthcoming paper will consider this effect in T Tauri disks (K. Wood et al. 2003, private communication).

The more embedded Class 0 sources have less scattered flux at optical/near-IR wavelengths because of higher extinction in the envelope and cavity, so the "dip" at 10 μm is not as striking in these sources. The Class 0 source shows little variation with inclination except for the pole-on source and at near-IR wavelengths. The Class III source also shows little variation with inclination because it is optically thin at all wavelengths. Examining the variation of SEDs with evolutionary state, we see a tendency for increased shortwave

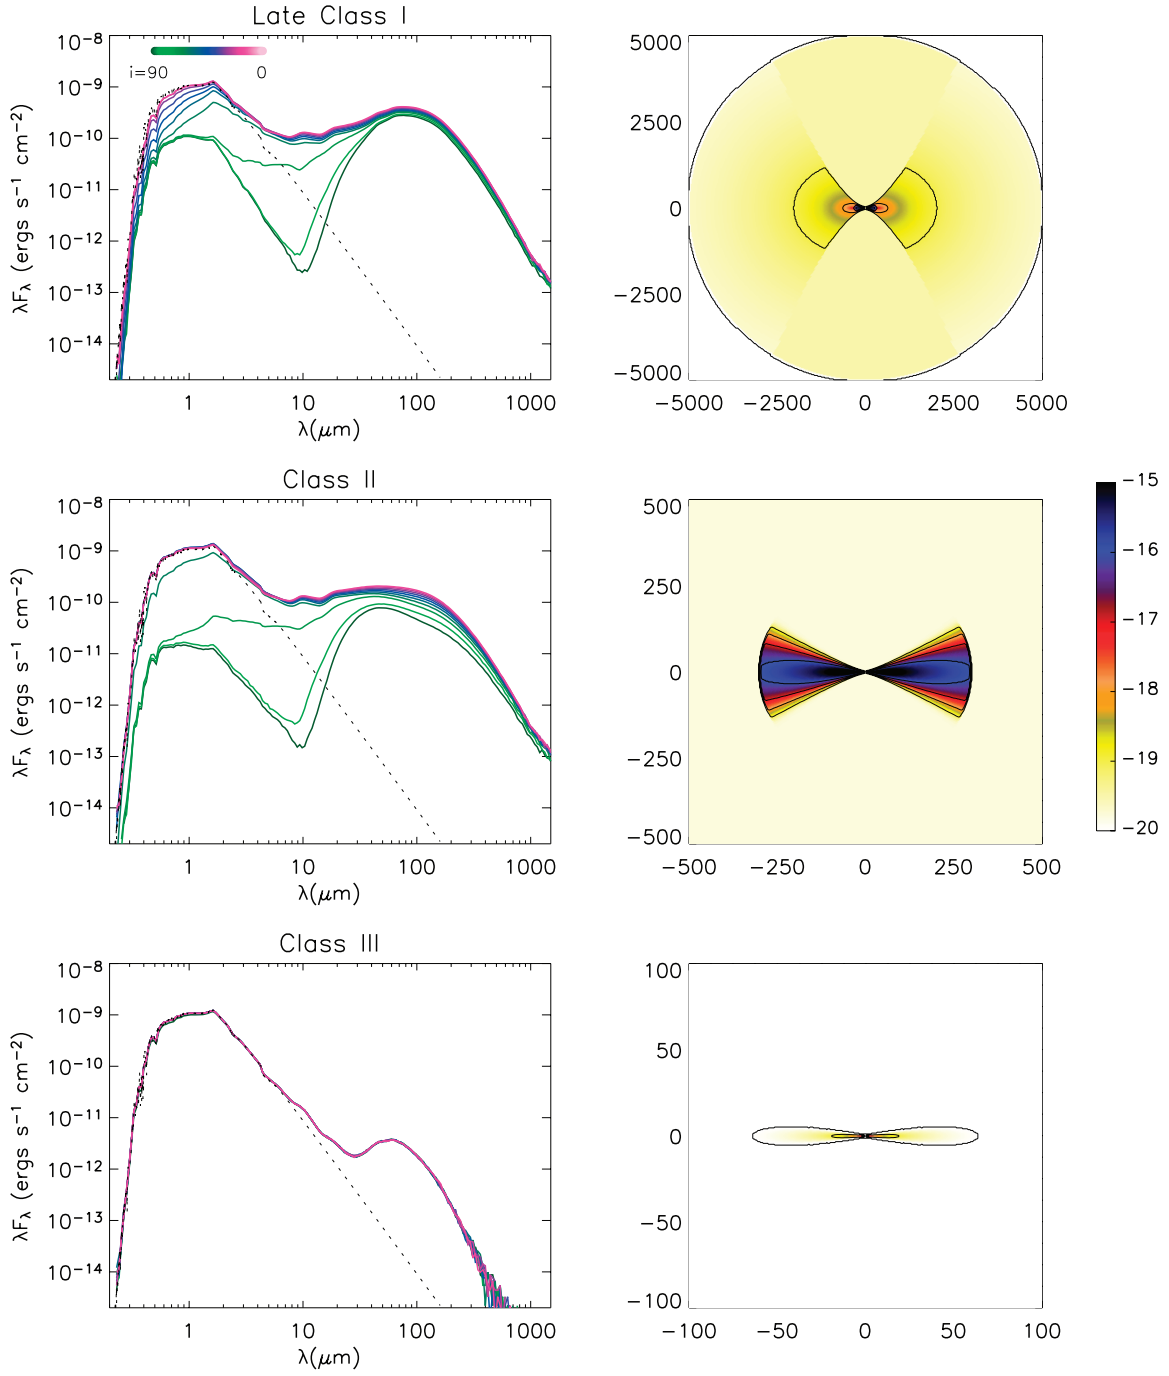

FIG. 3*b*

(0–10 μm) flux and decreased longwave (100–1000 μm) flux with age.

3.1.1. *Effect of Aperture Size*

As stated previously, the SEDs shown in Figure 3 include the flux emitted by the entire envelope. Normally, observed fluxes are integrated within a given aperture size. Figure 4 shows SEDs of the Class 0 and I sources computed in different aperture sizes, with 1000 AU radius apertures depicted by the solid lines and 5000 AU apertures by the dashed lines. The Class II and III sources are not shown since they are smaller than either of these apertures and thus do not vary in these apertures. Three inclinations are shown for each model ($i = 18°$, $56°$, $87°$) in three colors (*pink, blue, and green, respectively*). The large-aperture results show much more scattered flux at wavelengths less than 10 μm. The Class 0 source has no near-IR flux in the small aperture. This suggests that care should be taken in comparing different sets of observations with either different aperture sizes or different source distances.

3.1.2. *Class I/Class II Confusion*

Figure 5 shows that a low-luminosity Class I and a high-luminosity Class II source at different inclinations can resemble each other. Our Class II model was scaled up by a factor of 5 to get the fluxes to agree with the Class I model.

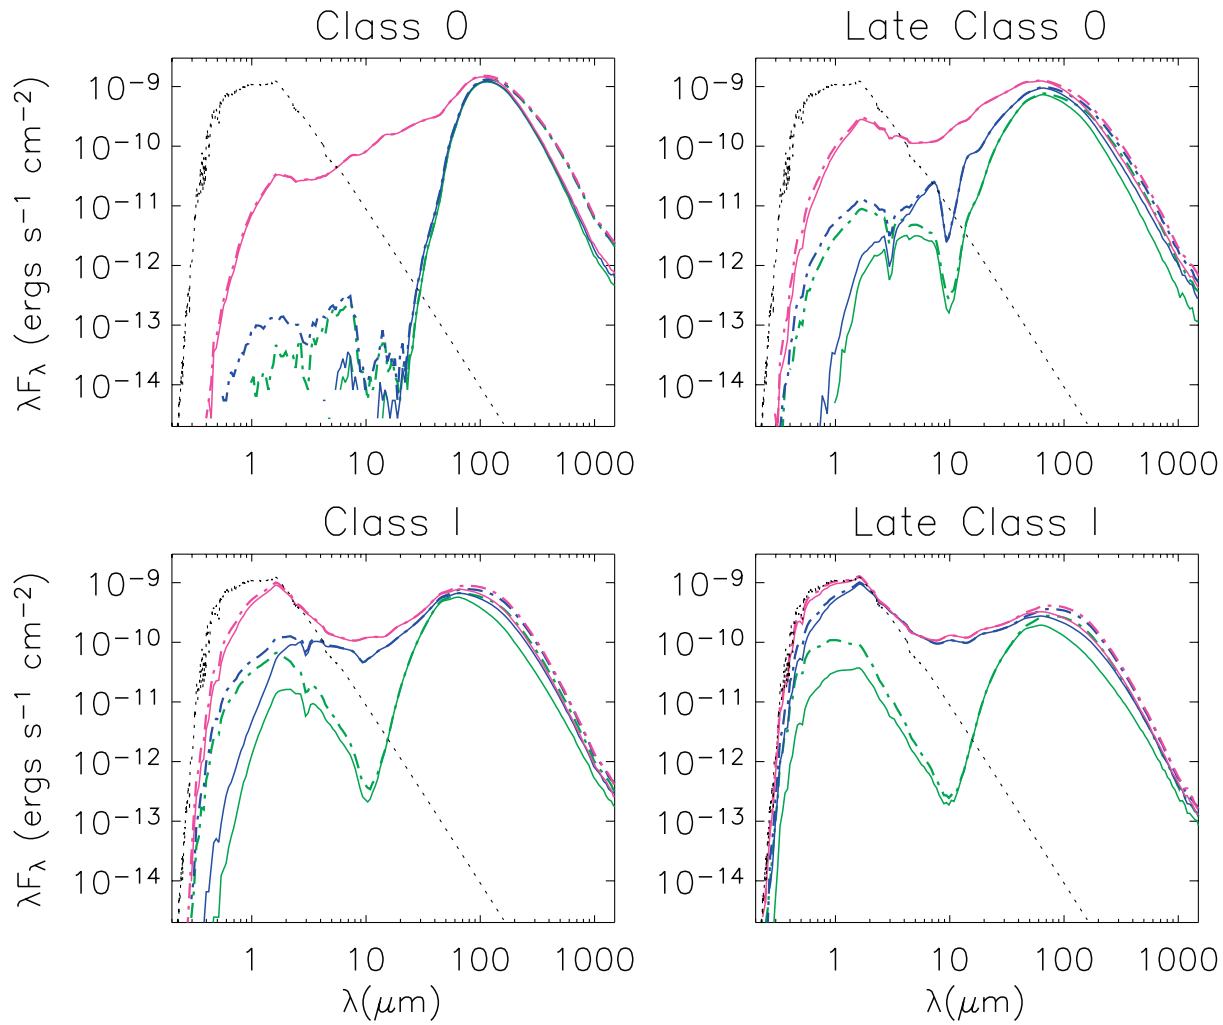

FIG. 4.—Comparison of SEDs computed in different aperture sizes for the sources with envelopes (Classes 0–I). Small-aperture results (1000 AU radius) are shown as solid lines, and large-aperture results (5000 AU radius) are shown as dot-dashed lines. Three inclinations are plotted for each model ($i = 18°$, 56°, 87°) as separate colors (*pink, blue, and green, respectively*).

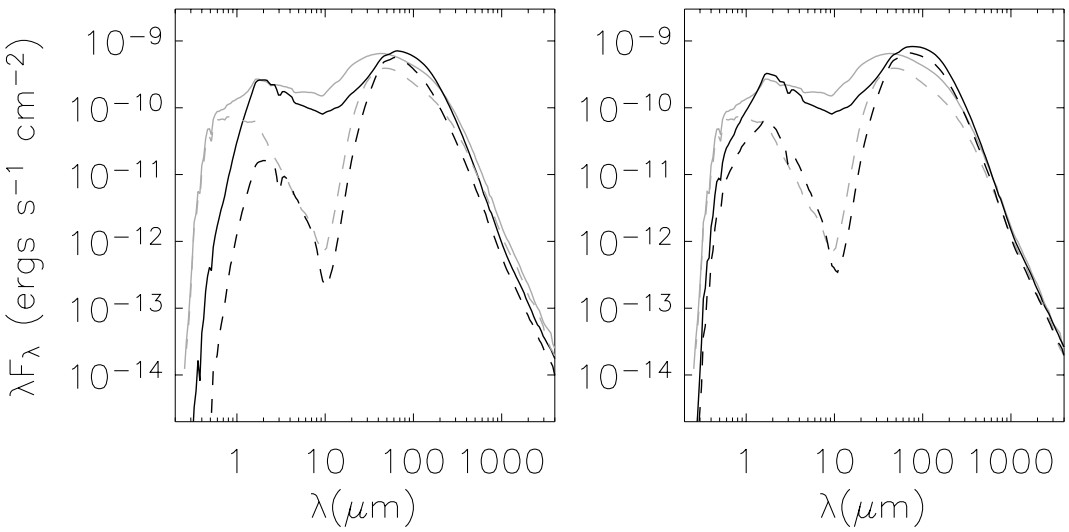

FIG. 5.—SEDs at selected inclinations for a Class I source (*black*) and a Class II source (*gray*). The luminosity of the Class II source is scaled up by a factor of 5. The Class I results are shown for apertures of 1000 AU at left and 5000 AU at right. The dashed lines show inclinations of $i = 87°$ for the Class I and II sources. The solid lines show inclinations of $i = 41°$ for the Class I source and $i = 75°$ for the Class II source.

This gives higher far-IR flux than the Class I source but better agreement in the near-IR, where the Class I source scatters more light from its large envelope. The black lines correspond to a Class I source, and the gray lines are a Class II source. The dashed lines show both sources at an inclination of $i = 87°$, or nearly edge-on. The solid lines show the Class I source at $i = 41°$ and a Class II source at $i = 75°$. In both cases, the Class II source is viewed fairly close to edge-on, so the central source is obscured at visible wavelengths. In the left panel, the Class I fluxes are summed in the 1000 AU radius aperture, and at right, the fluxes are summed in the 5000 AU aperture. The smaller aperture results do not show as much agreement. Thus in nearby star formation regions, it is possible to distinguish Class I and II sources on the basis of images and aperture photometry. However, in far-away star formation regions where the Class I source may not be spatially resolved, it may not be so easy to distinguish without additional information such as polarization (§ 3.3).

3.1.3. *Grain Properties*

Figure 6 shows the effects of varying grain properties in the different regions of the disk/envelope. The solid lines show our standard models used throughout this paper, with the different grain models in the four different regions (Fig. 1). The gray line plots models that have the envelope grains throughout the disk/envelope/cavity. In models where the envelope emission (and scattering) dominates, we should see little difference between the SEDs. This is the case for the Class 0 source, which shows a difference only at optical/near-IR wavelengths for the pole-on source, due to the slightly higher extinction in the cavity of the envelope grains compared with the outflow grains. The late Class 0 source shows less of this effect because of lower cavity density, but it shows a difference at wavelengths longer than 100 μm for more pole-on viewing angles. This is because some disk emission can emerge into pole-on inclinations at long wavelengths, and differences in the grain properties between the two models are apparent. The Class I–II sources show more differences at these wavelengths, especially at pole-on inclinations.

In more evolved or pole-on sources, more disk radiation can penetrate through the envelope. This difference is greatest in the Class II source, where emission comes only from the disk, and therefore different grains in the disk have a noticeable effect on the longwave SED. Edge-on, we can see differences near 10 μm in the late Class I–III sources due to the different extinction opacities in the disk. The Class III models show little difference because the disk is optically thin, and the multigrain model (*black*) uses the disk atmosphere grains (Table 3 and Fig. 2), which are not substantially different from the envelope grains.

Note that we have not attempted to created a realistic grain model for a Class III source that would compute size distributions based on shattering models. More detailed models can be found in Kenyon et al. (1999); Augereau et al. (1999); Wolf & Hillenbrand (2003); and Li & Lunine (2003).

To turn the results of Figure 6 around, grain growth in the disk is not detectable in the SEDs of Class 0 sources, because of the dominance of envelope emission. Grain growth is detectable in Class I sources by the slope of the longwave emission (>100 μm), which is flatter for large grains in a manner similar to Class II disks (Beckwith, Henning, & Nakagawa 2000). These results agree with those of Wolf et al. (2003), who fitted near-IR images of the IRAS 04302+2247 with ISM-like grains in the envelope but required large grains in the disk to fit the submillimeter images.

3.2. *Colors and Magnitudes*

In anticipation of *SIRTF* observations, we show in Figures 7 and 8 colors and magnitudes for the near-IR *J*, *H*, and *K* bands; the mid-IR *SIRTF* IRAC bands at 3.6, 4.5, 5.8, and 8 μm; and the far-IR *SIRTF* MIPS bands at 24, 70, and 160 μm. We also show *N*-band (10 μm) magnitudes for comparison with current ground-based observations. The colored points are our models, with colors corresponding to evolutionary state as shown in the legend at top left. The sizes of the circles correspond to inclination from pole-on (large) to edge-on (small). In Figures 7*a* and 8*a* the fluxes have been computed in an aperture size of 1000 AU radius, or 7.″1 at a distance of 140 pc. Figures 7*b* and 8*b* show results for a 5000 AU radius aperture. These plots make it clear that in comparing results of star formation regions at different distances, the aperture size should be taken into account.

All of the models have fluxes brighter than 1 μJy at the wavelengths shown except for some of the Class 0 points, which are fainter at wavelengths smaller than 5 μm. For these sources, we show fluxes as faint as 0.01 μJy to account for the possibility of a high-luminosity Class 0 source in a nearby star-forming region. Most of the shortwave Class 0 fluxes are too faint to show in the small-aperture plots (Fig. 7*a*) except at long wavelengths or pole-on inclinations.

3.2.1. *Distinguishing Protostars from Other Point Sources*

The small black symbols in Figure 7 are computed colors of a variety of different kinds of object based on complete 1–35 μm infrared spectra using the SKY program (Wainscoat et al. 1992; Cohen 1993). The crosses correspond to main-sequence, red giant, and supergiant stars; the diamonds are AGB stars; the squares are planetary nebula; the asterisks are reflection nebulae; the small cross is an H II region; and the big cross is a T Tauri star (Cohen & Witteborn 1985). Since the SKY spectral library does not exist at wavelengths longward of 35 μm, the bottom right panel of Figure 7 does not show SKY results. This figure shows a lot of overlap between our predicted star formation colors and those of AGB stars and planetary nebulae. However, the bottom left panel, [3.6]–[5.8] versus [8.0]–[24], shows significant separation. For the most part, the main-sequence, red giant, and supergiant stars are well separated from the star formation models. The arrows show reddening vectors for the standard diffuse ISM law (*in gray*) and for our envelope dust model, more representative of dark clouds. In the near-IR, the star formation points will overlap with reddened main-sequence and other sources (*top two panels*). However, several of the mid-IR panels show reasonable separation from reddened Galactic point sources, especially the bottom left panel again. The overlap with AGB stars, planetary nebulae, and reflection nebulae is a problem only for distant star formation regions in the Galactic plane, where we may expect to see a total of no more than 300 of these sources per square degree.

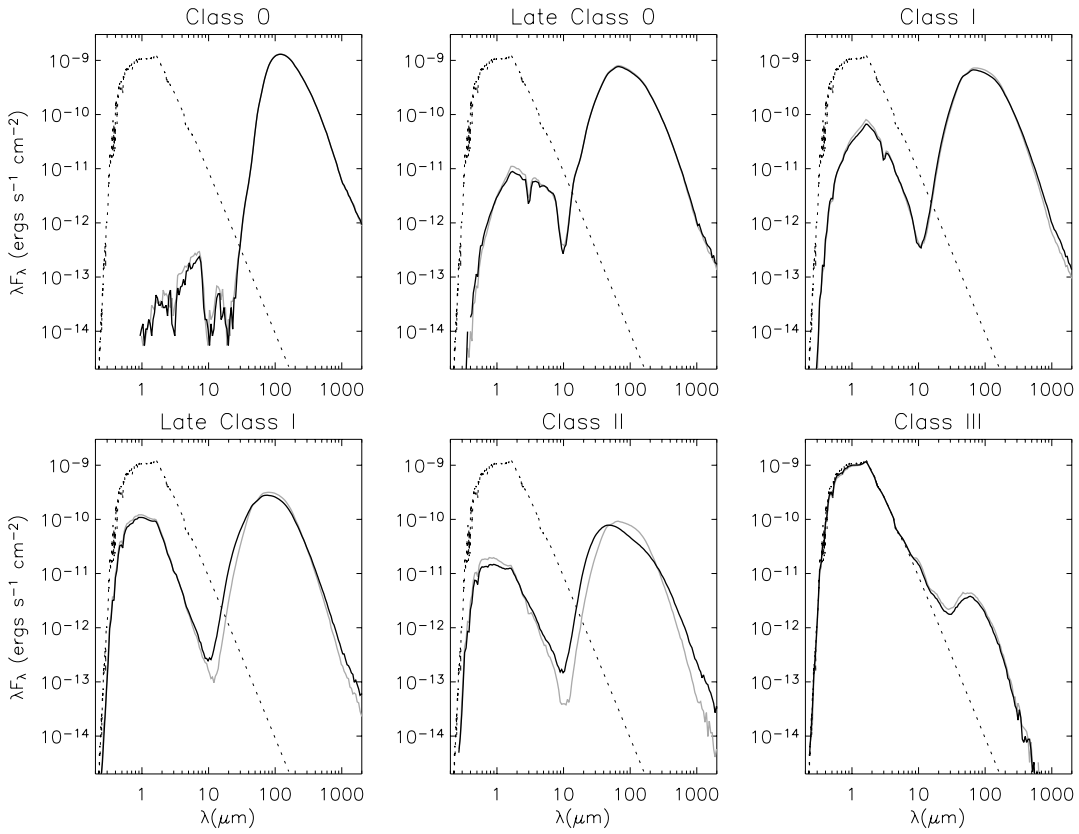

FIG. 6*a*

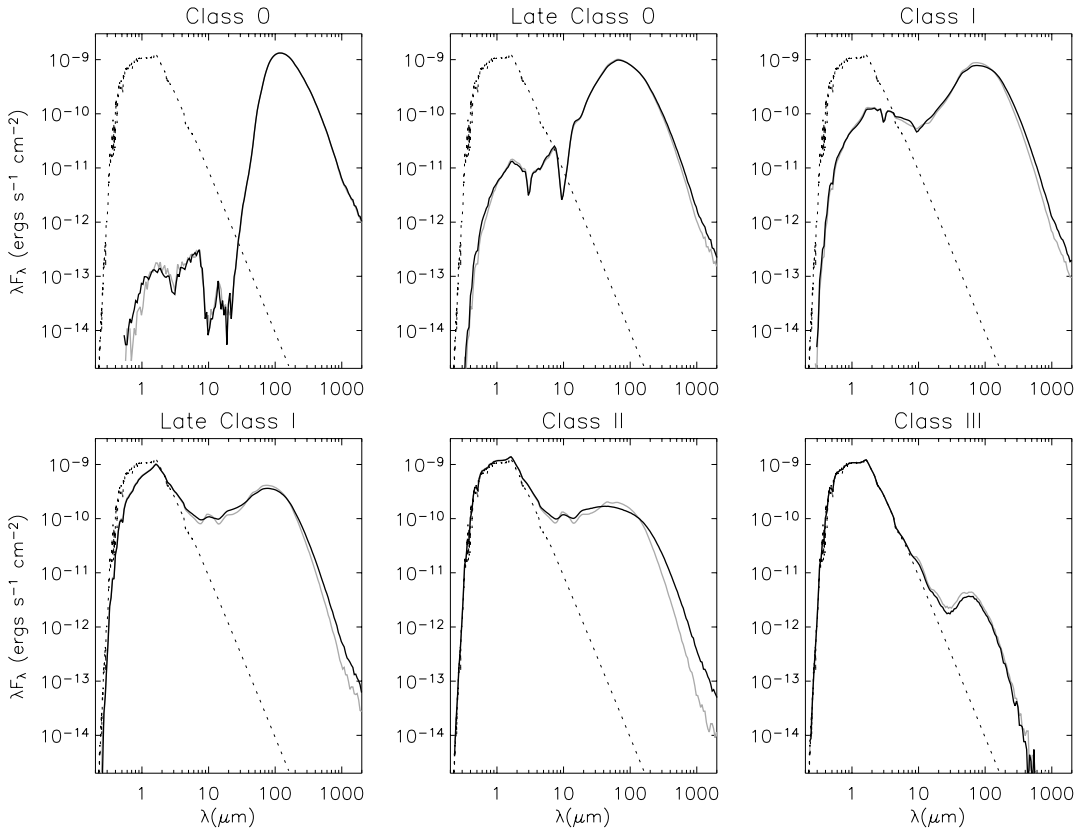

FIG. 6*b*

FIG. 6.—Comparison of the SEDs produced from the different dust models. The black line plots the results from using different dust models for the four different regions (see Fig. 1 and Table 3). The gray line shows results using the Envelope dust ($r_v = 4.3$) throughout. (*a*) Inclination is $i = 87°$ (edge-on); (*b*) inclination is $i = 56°$; (*c*) inclination is $i = 18$ (pole-on).

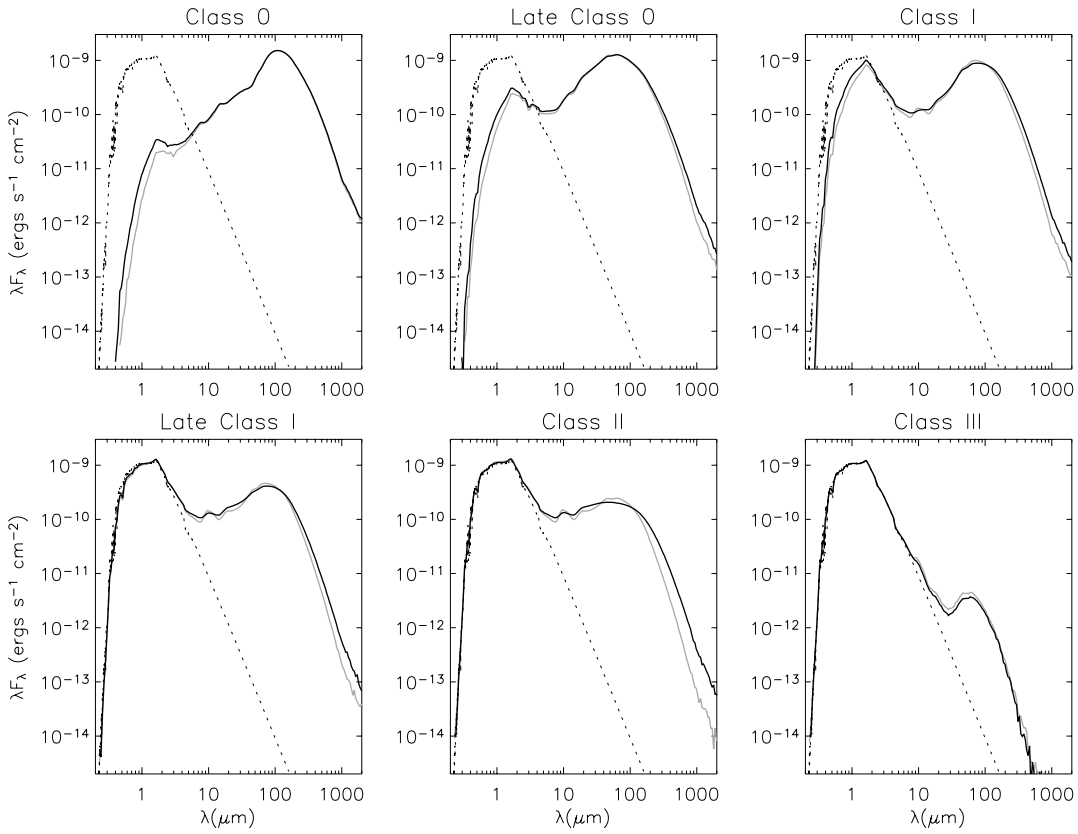

FIG. 6*c*

3.2.2. *Distinguishing Protostellar Evolutionary States*

How well do the colors distinguish evolutionary states in the star formation models? In general, the younger sources appear to be more red, although there is overlap due to inclination effects and aperture size (Fig. 7*b*). As Figure 4 showed, the Class 0 source has little measurable flux below $\sim 5\mu$m for all but the pole-on source. Thus for many of the panels, only the pole-on inclination is shown in Figure 7*a*, the smaller aperture results. In the near-IR sequences (*top two panels*), the pole-on Class 0 point falls in the middle of the other models. At longer wavelengths, the Class 0 points that are observable (*in dark blue*) tend to lie in a separate region from the other sources, in the small-aperture results (Fig. 7*a*). However, in the large-aperture results of Figure 7*b*, the Class 0 sources are in many cases *bluer* than the more evolved sources, even some of the Class III sources, especially at $K-N$, [5.8]–[8.0], and [8.0]–[24] in Figure 7*b*. This shows again the importance of considering aperture size because of the contribution of scattered light on large scales in the envelope, especially in the youngest sources. The Class 0 points are redder in K–[3.6] and [3.6]–[4.5], but only by about 0.5–1 mag. They are much redder at [24]–[70], as shown in the bottom right of Fig. 7*b*.

Notice that the bluest sources are edge-on Class I sources in several of the near-IR and mid-IR sequences (*top four panels*). This is true for both the small- and large-aperture results. The reason for this is that the edge-on disk blocks all of the reddened stellar flux, leaving only the scattered flux from the envelope, which is relatively blue (owing to decreasing scattering opacity with increasing wavelength).

3.2.3. *Comparison to Observed Color-Color Diagrams*

The $J-H$ versus [3.6] and K–[3.6] versus $K-N$ can be compared with ground-based observations of $J-H$ versus $K-L$ and $K-L$ versus $K-N$, for example the Taurus-Aurigae cluster at 140 pc (Wood et al. 2002a) and the NGC 2024 cluster at a distance of 415 pc (Haisch et al. 2001). The Taurus cloud is sufficiently nearby for our small-aperture results to apply, and indeed our results in Figure 7*a* agree with those shown in Wood et al. (2002a, their Fig. 7). It is interesting to note that our large-aperture K–[3.6] versus $K-N$ plot includes Class 0 sources in the same region in which the Haisch et al. estimate Class II sources to lie. In the $J-H$ versus K–[3.6] panel, the Class 0 sources also fall in the same region in which Haisch et al. estimate Class I sources to lie (their Fig. 7). And the Class I sources overlap with the Class II source region. Thus, in more distant star formation regions, it will be more difficult to separate evolutionary states by their colors alone. We emphasize that scattered light, especially when measured in large apertures or distant sources, makes Class 0 and I sources appear much bluer than is perhaps generally thought.

3.2.4. *Color-Magnitude Diagrams*

The sequences in Figure 8*a*, the 1000 AU radius aperture results, show that in general the edge-on sources are fainter and the younger sources are redder. Note the large range in magnitude (y-axis) for all of these sources, despite the fact that *all of these models have the same luminosity*. Even more striking is the variation in magnitude from a given model due to inclination. Not surprisingly, this effect is larger for

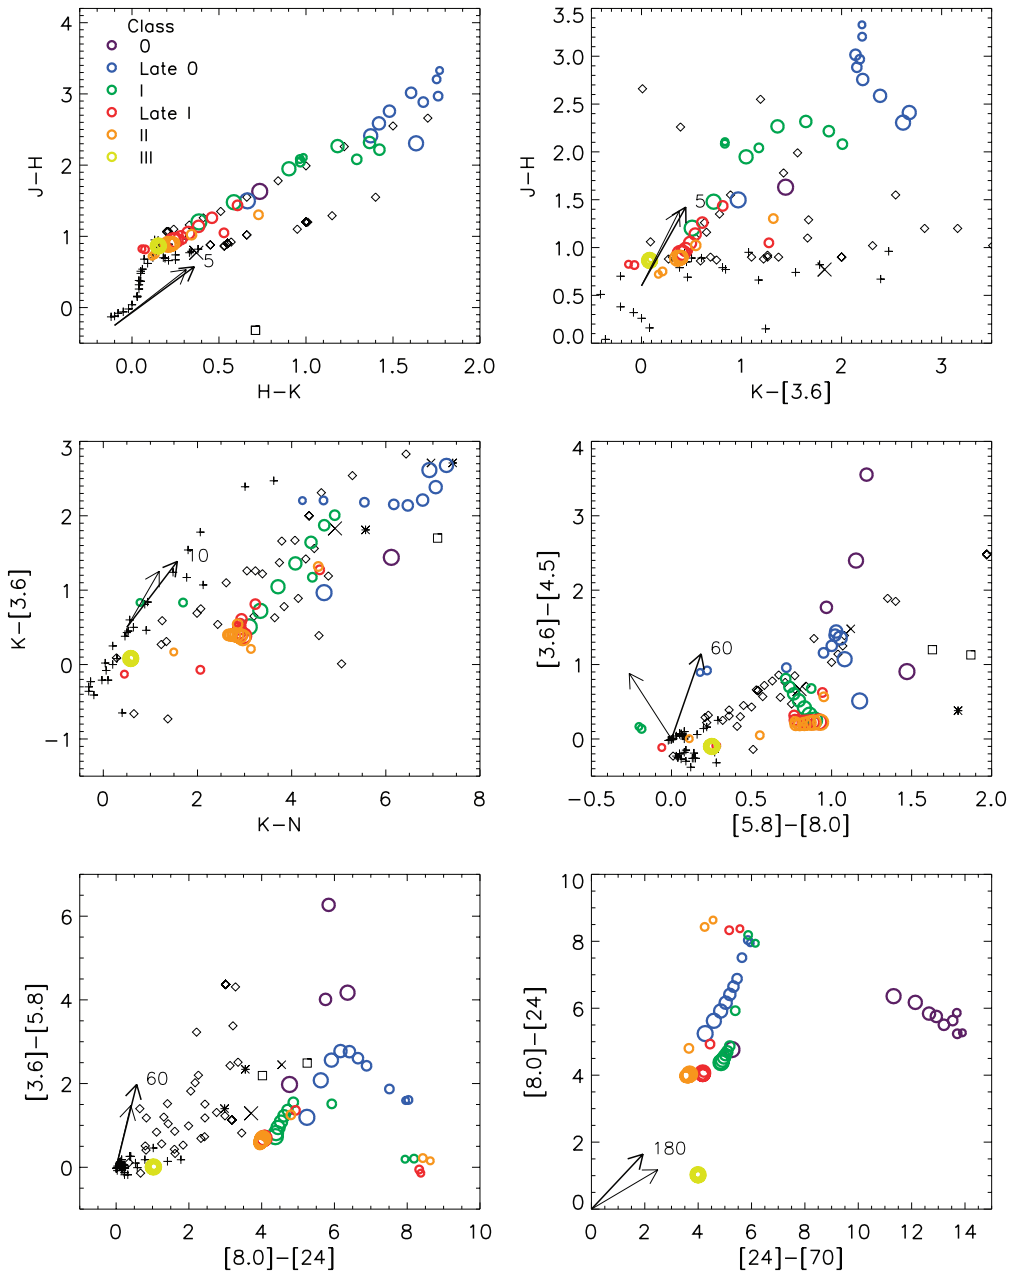

Fig. 7*a*

Fig. 7.—Color-color plots. The legend in the top left panel shows the color correspondence with the evolutionary sequence. The symbol sizes vary with inclination with edge-on the smallest. Arrows show the reddening vectors for standard ISM dust (*gray arrow*) and dust more representative of dark clouds with $r_v = 4$ (our envelope grains; *black arrow*). The black symbols are predictions for other stellar types as follows: *crosses*, main-sequence, red giant, and supergiant stars; *diamonds*, AGB stars; *squares*, planetary nebulae; *asterisks*, reflection nebulae; *small crosses*, H II region; *large crosses*, T Tauri star. (*a*) Aperture size is 1000 AU radius. (*b*) Aperture size is 5000 AU radius.

the younger sources because of their large variation of extinction with inclination. As expected, the Class II and III sources have fairly constant flux with inclination until they become edge-on. Because the edge-on sources are fainter, they could be mistaken for much lower luminosity sources such as brown dwarfs (Walker et al. 2003). The variation of magnitude with inclination is much smaller at 70 μm because of the lower envelope/disk extinction and more isotropic thermal emission.

Figure 8*b* shows again the overlap in colors of all the evolutionary states when viewed through large apertures (5000 AU radius). At $J-K$, the Class 0 source has the same colors as a Class II and III source. At [5.8]–[8], the Class 0 source is bluer than all except the edge-on Class I and II sources. The [3.6]–[5.8] sequence shows more spread, but notice that the entire evolutionary sequence ranges within 3 mag. Since these models all have the same luminosity, the Class 0 sources are faintest in the near- to mid-IR because of large envelope extinction. The Class III source is well separated at [24]–[70] and [70]–[160].

Since the lifetimes of Class II sources are 10–100 times longer than Class 0 and I sources, we expect observed color-color and color-magnitude diagrams to be dominated by Class II and III sources. Since 90% of these sources are

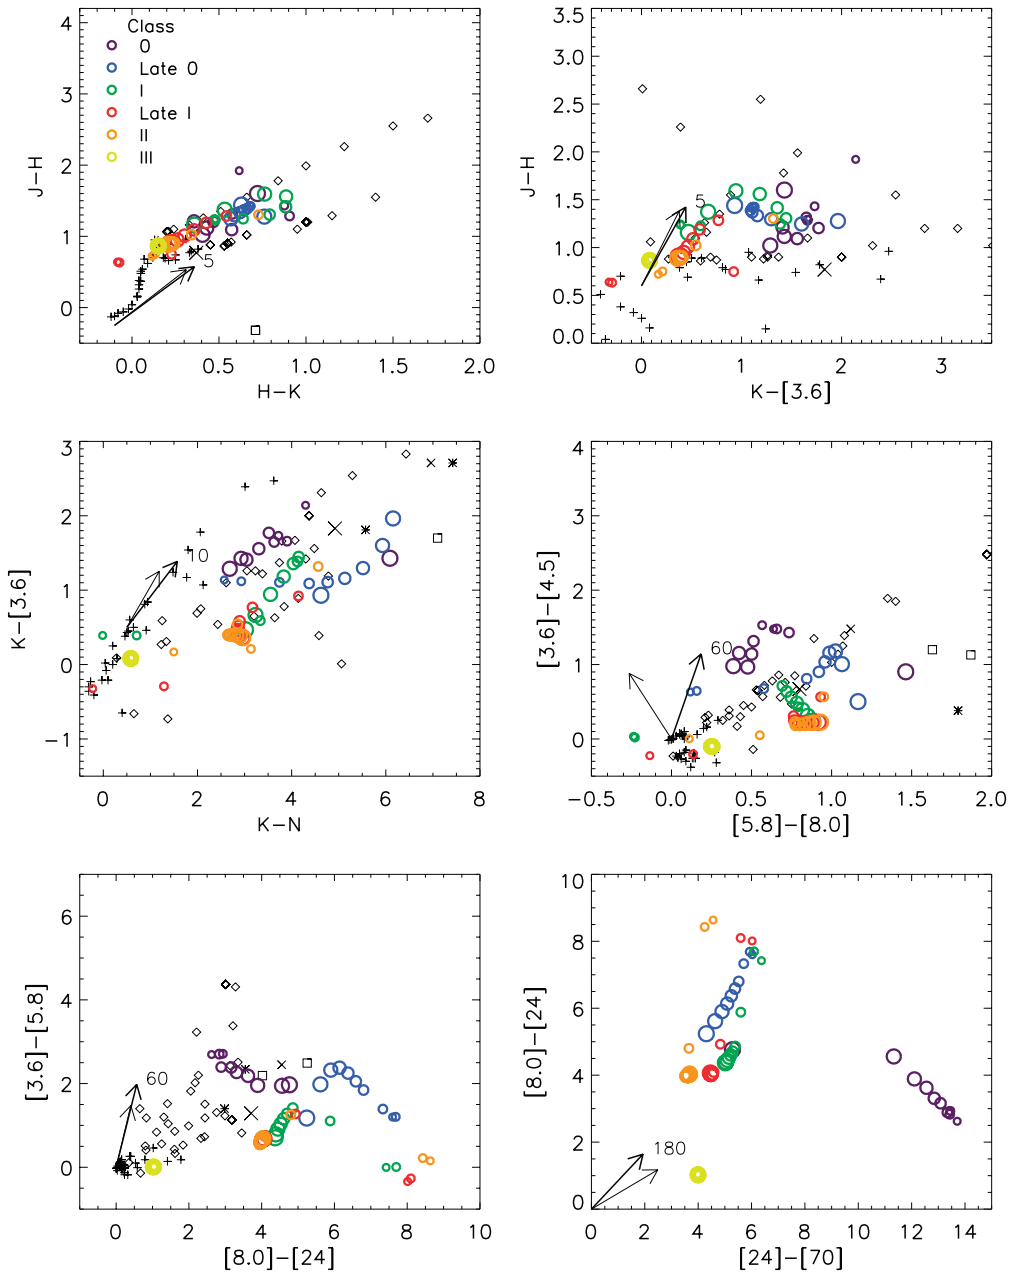

FIG. 7*b*

viewed at unobscured inclinations, their fluxes can be used to estimate luminosity. The caution is that there is perhaps a 15% contamination in these diagrams due to younger sources (Class 0 and I) that appear blue because of scattering.

3.3. *Polarization*

Figure 9 shows polarization plots for four of the evolutionary sequences. The Class 0 models did not have a high enough signal-to-noise ratio to show the spectral results (current observing technology would probably suffer similar difficulties.) The polarization of the Class III model is less than 0.2% so is not shown. In these models, the polarization arises from scattering from spherical grains in an asymmetric envelope geometry. There is no component due to aligned grains (see Whitney & Wolff 2002 for models of scattering from aligned grains, and Aitken et al. 2002 for models that include emission from aligned grains). In the Class 0 and I sources, more radiation escapes the polar regions than the equatorial, giving rise to polarization with a position angle oriented perpendicular to the rotation axis (the z-axis). In the Class II sources, most of the scattering takes place in the disk plane. Viewed at most inclinations the polarization is oriented perpendicular to the disk plane or parallel to the rotation axis. We define $Q = P\cos 2\chi$, where χ is measured from the rotation axis. Because χ is either 0° or 90° in these axisymmetric models, we can display it as Q that is either negative or positive. For Class 0 and I sources the Q polarization is mostly negative, and for Class II sources it is mostly positive as shown in Figure 9. The polarization is highest toward edge-on inclinations where the unpolarized central stellar flux becomes more extincted and the envelope scattering geometry is most asymmetric.

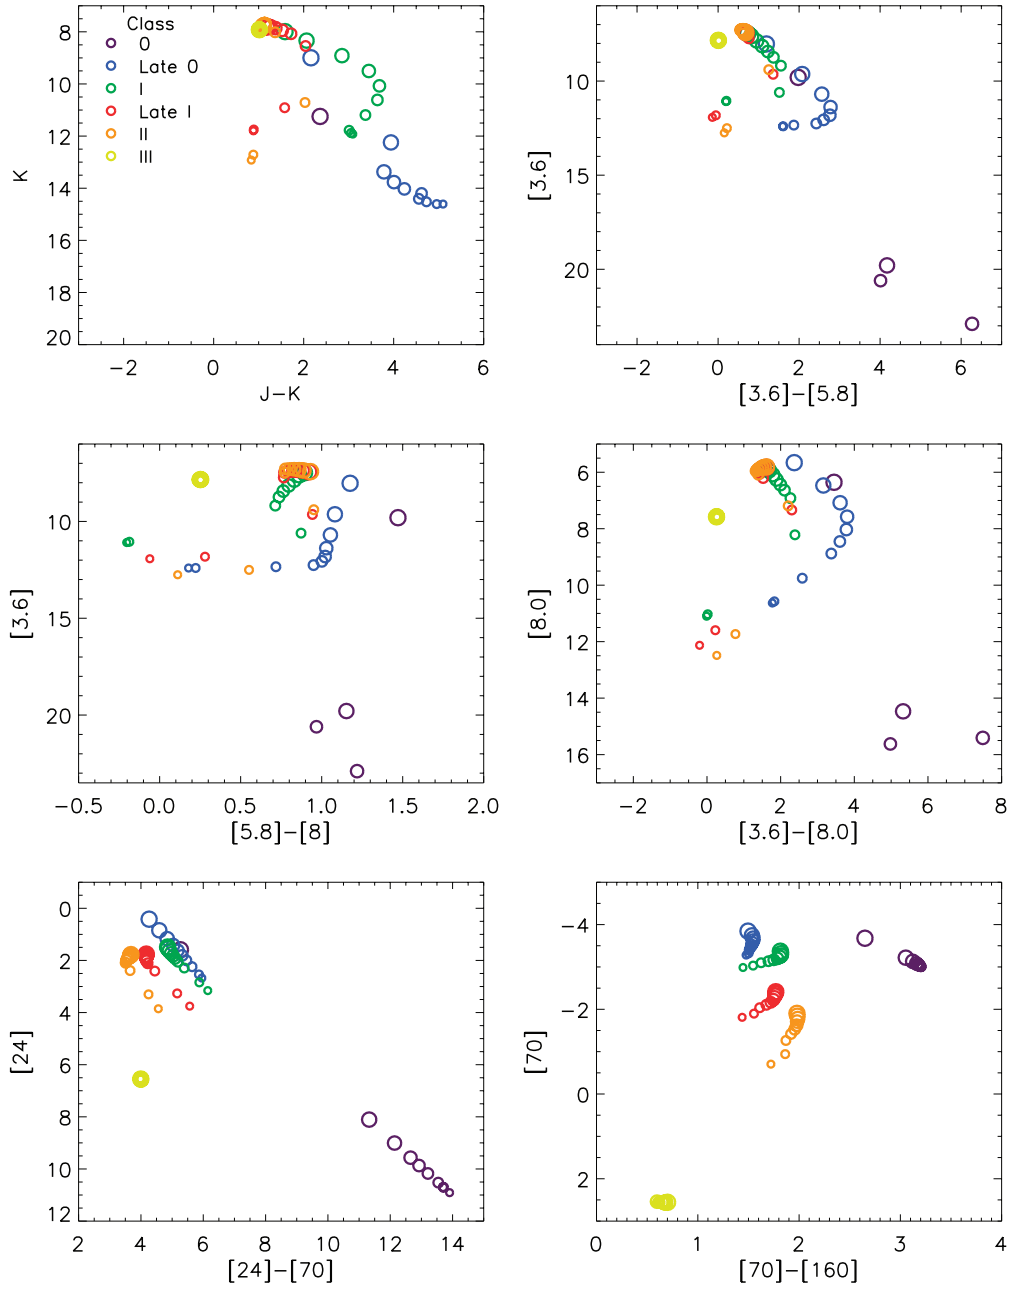

FIG. 8*a*

FIG. 8.—Color-magnitude plots. The legend in the top left panel shows the color correspondence with the evolutionary sequence. The symbol sizes vary with inclination with edge-on the smallest. (*a*) Aperture size is 1000 AU radius. (*b*) Aperture size is 5000 AU radius.

The wavelength dependence of the polarization is due to several grain properties, especially the opacity, scattering albedo, and polarization efficiency. The polarization spectrum of the late Class 0 source is inversely correlated with the envelope extinction (or dust opacity; see Fig. 2, *top left*). The more the central unpolarized flux is extincted, the higher is the polarization of the emergent radiation. Thus the polarization rises across the 3.1 μm water ice feature and the 9.8 μm silicate feature. Between 3 and 8 μm it decreases because of decreasing envelope extinction, as well as decreasing scattering albedo. A competing effect is the polarization efficiency (Fig. 2, *bottom right*), which increases from 1 to 10 μm. In the late Class 0 source, the envelope is still opaque at 10 μm, so even though the scattering albedo is very low, there is essentially no unpolarized stellar flux to dilute the faint scattered flux. Thus the polarization is higher at 10 μm than at any other wavelength because of the increased polarization efficiency. In practice, measurement of polarization at this wavelength may be difficult because of the correspondingly low fluxes.

In the Class I source, the polarization increases at 10 μm for the edge-on case where the disk extincts all stellar flux, but it is not as high as at 1 μm. This is because the envelope-scattering geometry is more asymmetric at 1 μm than at 10 μm. At 10 μm the emerging flux comes from a wider angular range because of lower overall extinctions. In the late Class I and II edge-on sources, the polarization is large and positive ($Q > 0$) over a large range in wavelength, peaking near

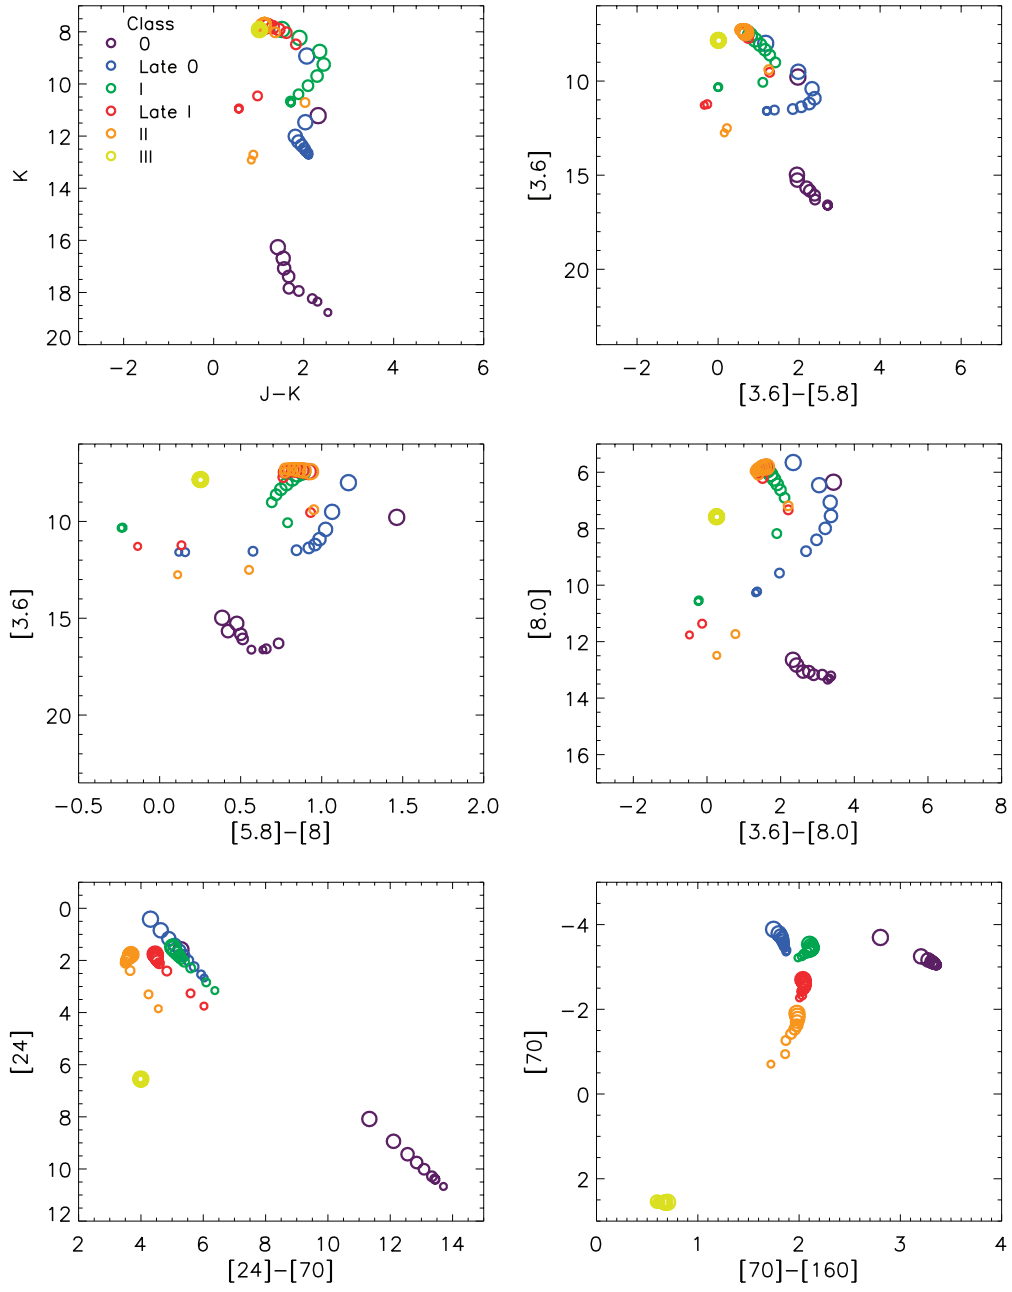

FIG. 8*b*

9 μm. At these wavelengths, most of the scattered (polarized) light emerges from the disk plane. The polarization is negative ($Q < 0$) at visible wavelengths in the edge-on Class II source because of a higher amount of scattering from the ambient cloud in the polar regions. Since our disk grains do not include the water ice features, there is no feature in the polarization spectrum in the disk-only models.

The large polarization values in Figure 9 suggest that near-IR polarization measurements could provide a way to disentangle the overlap in the colors of sources of different evolutionary states, especially in the large-aperture results. Figure 10 shows the same results as in Figure 7*b*, except that the size of the symbols correspond to the *K*-band polarization of that source computed in the same aperture size as the flux. It is clear from this figure that the Class 0 sources can be separated from the other evolutionary states on the basis of their *K*-band polarization. The edge-on Class I and II sources also show measurable (5%–10%) polarization. Thus, we can see that if the very blue sources also have significant polarization, they are likely edge-on Class I and II sources. This provides a way to distinguish these sources from brown dwarfs.

3.4. *Images*

Figure 11 shows three-color images of our evolutionary sequence at selected wavelength ranges. The images have been computed through passbands corresponding to the *Hubble Space Telescope* (*HST*) NICMOS near-IR filters F110W, F160W, and F205W with approximate central wavelengths of 1.0, 1.6, and 2.0 μm, and the *SIRTF* mid-IR IRAC and MIPS filters at approximately 3.6, 4.5, 5.8, 8,

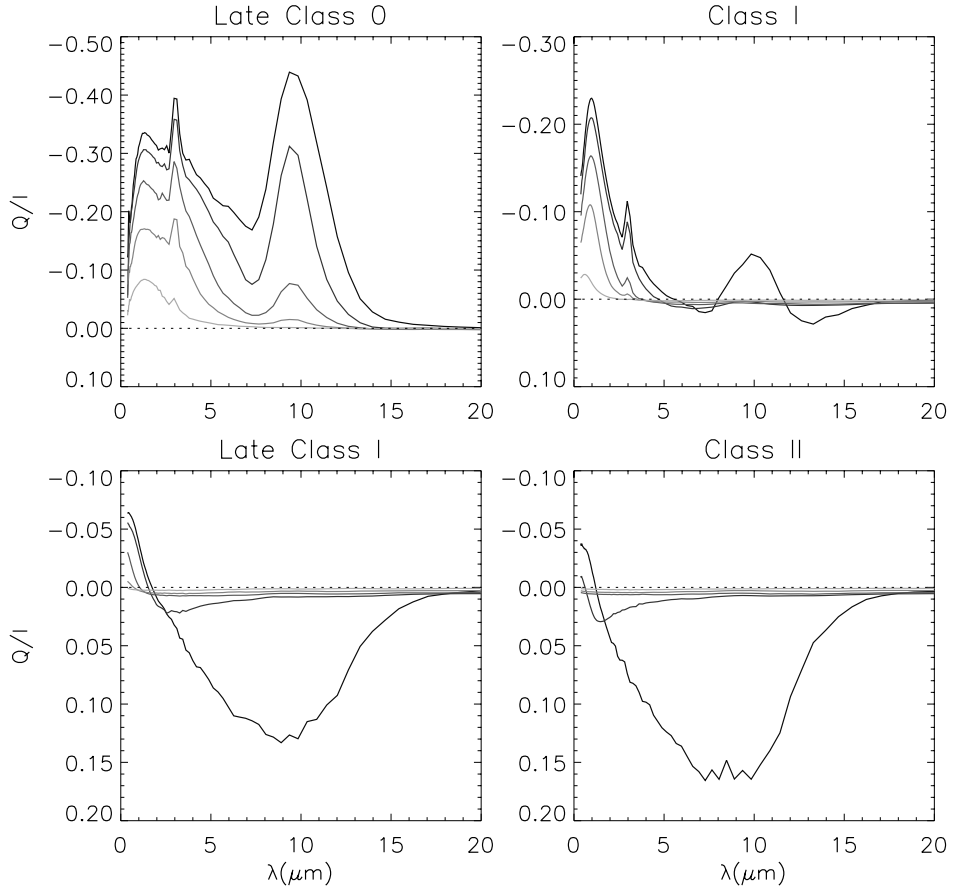

FIG. 9.—Polarization. Five inclinations are plotted from $\cos i = 0.05$ to 0.85 in intervals of 0.2. The lines are lighter gray at lower inclinations (more pole-on).

and 24 μm. The images are displayed as "true-color" images with the shortest wavelength image in blue, the middle in green, and the longest in red. The near-IR images are combined in the left panels of Figure 11. In the middle panels, the *SIRTF* IRAC bands are combined with the 3.6 μm image in blue, the 4.5 and 5.8 μm images averaged together in green, and the 8.0 μm image in red. In the right, the 8.0, 24, and 70 μm images make up the three color planes. The displayed spatial resolution of the images in Class 0–I sources is 0.″4 FWHM, which is finer than that expected from the *SIRTF* IRAC camera by about a factor of 4. The displayed resolution of the Class II and III sources is 0.″1and 0.″04, respectively.

The images are viewed at an inclination angle of 80°, showing the inner 2000 AU for the envelope sources (Classes 0–I), 500 AU of the Class II source, and 200 AU for the Class III sources. The intensities are scaled to a source luminosity of 1 $L_\odot$ and a distance of 140 pc. In Figure 11*a* the minimum intensities displayed are 0.06, 0.03, and 15 MJy sr^{-1} from left to right, for the Class 0–I sources.[5] The peak intensities displayed are as high as 10^4 times higher than the minimum intensities, although in many of the edge-on sources, the peak intensity is only 100–1000 times higher than the minimum intensity. The Class 0 source shows no detectable near-IR emission at the displayed intensities.

[5] 1 MJy sr^{-1} = 23.5 μJy arcsec^{-2}.

The near-IR images are similar to those presented by Stark et al. (2003). The younger sources are redder. The Class 0 source is not detected at near-IR wavelengths at the sensitivities shown here. As pointed out by Stark et al., the disk in the late Class I source casts a shadow much larger than the disk size itself. Hodapp et al. (2003) see a similar feature in the object ASR 41.

The *SIRTF* IRAC diffuse source sensitivity is expected to be approximately 0.026 MJy sr^{-1} at 5.8 μm and lower in the smaller wavelength bands (*SIRTF* Observing Manual). Thus, the diffuse emission from edge-on protostars in nearby star-forming regions should be detectable with *SIRTF*. The mid-IR images (*middle panels*) tend to be blue and the far-IR images (*right panels*) are red. This is most striking in the Class I–II sequence. Given that the SEDs of these sources show a large dip centered at about 10 μm, this result is understandable. The diffuse emission on large scales in the mid-IR images (*middle panels*) is due to scattering. The envelope grains (Fig. 2, Table 3) have enough mid-IR albedo to give large detectable scattering nebulae in the envelope sources. As discussed in Paper I, models of mid-IR images should provide useful information on the albedo and therefore on the grain sizes of protostars. The mid-IR images of Class II sources will also provide a useful test for the grain properties. As Figure 11*b* shows, the disk midplane thickness varies with wavelength because of the decrease in dust opacity with increasing wavelength. Comparison of near- and mid-IR images will provide direct

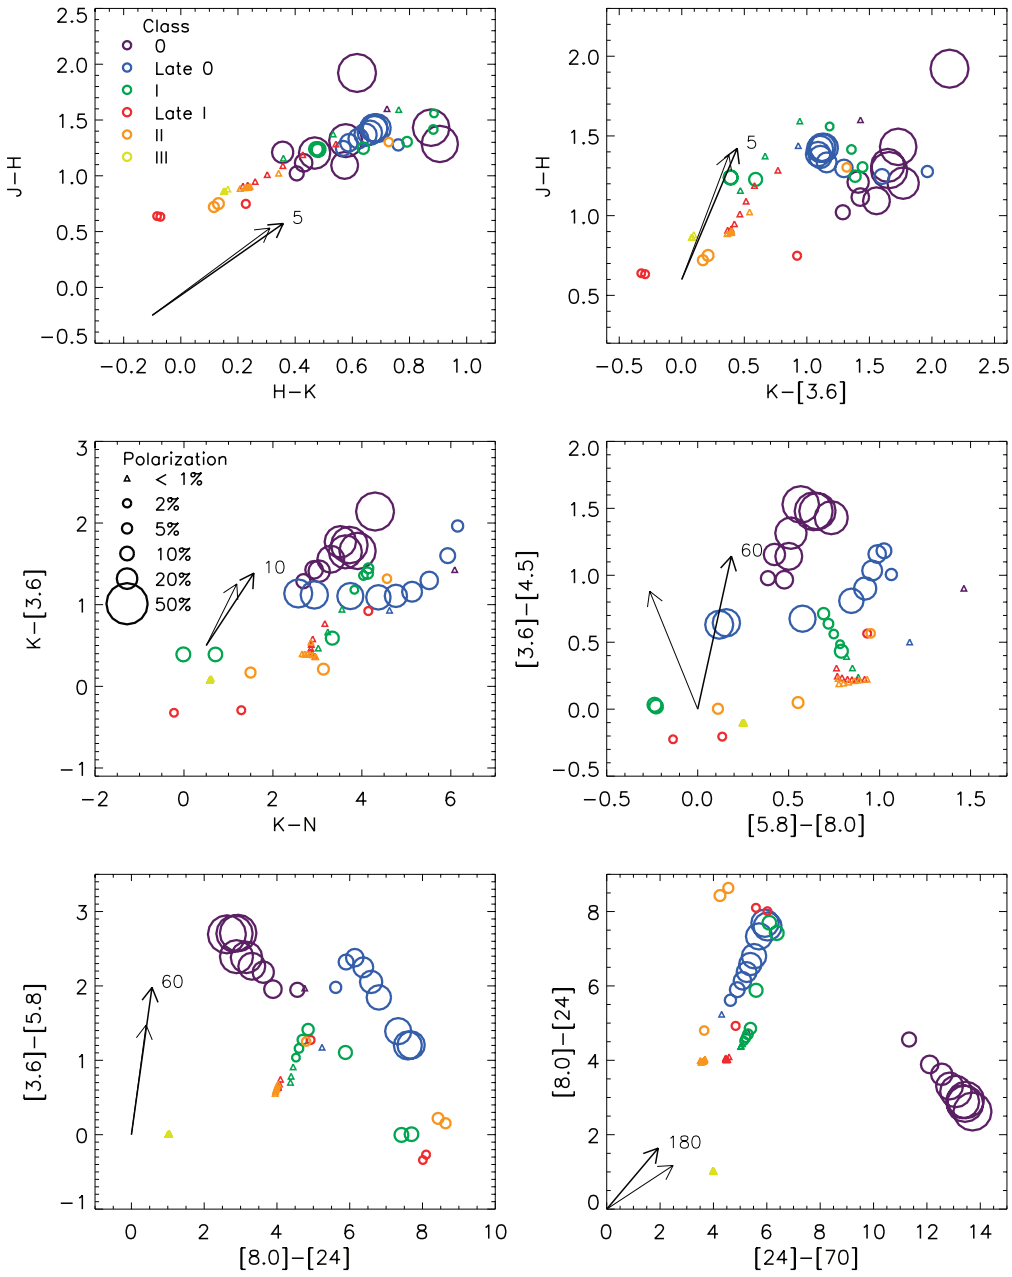

FIG. 10.—Color-color plots showing the large-aperture results (5000 AU). This is similar to Fig. 7*b*, except that the size of the symbols corresponds to the *K*-band polarization as shown in the legend in the middle left panel. Points with polarization less than 1% are plotted as small triangles. This shows that near-IR polarization can separate the Class 0 sources from others in the same region of color-color space.

information of the opacity variation with wavelength. Modeling the brightness of the scattering nebulae over this wavelength range will provide information on the dust grain sizes. For example, McCabe, Duchene, & Ghez (2003) have detected scattered light from the HK Tau B disk at 11.8 μm and concluded that grain sizes of 1.5–3 μm are required to produce the necessary scattered light.

The large-scale red emission in the far-IR images (*right panels*) is due to thermal emission at 70 μm. In the far-IR images, the 8 μm scattered light is very faint, and the 24 μm emission is confined to a smaller region, mainly the disk, as indicated by the yellow color in the center and in the Class II source (Fig. 11*b*, *top right*). We note that the spatial resolution at 70 μm shown here is much higher than will be obtained by *SIRTF* ($\sim$40″).

In Figure 11*b* the minimum intensities are 1, 1, and 80 MJy sr^{-1}, from left to right, for the Class II source, and 0.5, 0.3, and 40 MJy sr^{-1} for the Class III source. For the Class III source, the peak intensity from the star is about 1000 times brighter than the displayed peak in the near-IR (*left*) and mid-IR (*middle*) panels. That is, the dynamic range between the faintest intensity shown and the peak intensity is about 10 million for the near- and mid-IR images. The corresponding dynamic range for the far-IR image (*right*) is 10^5. The stellar size shown in these images has a FWHM of 0.″1. Thus detection of the diffuse flux would require some combination of high dynamic range, masking of the central source, excellent stellar point-spread function subtraction, or adaptive optics techniques. Also of interest is the fact that the

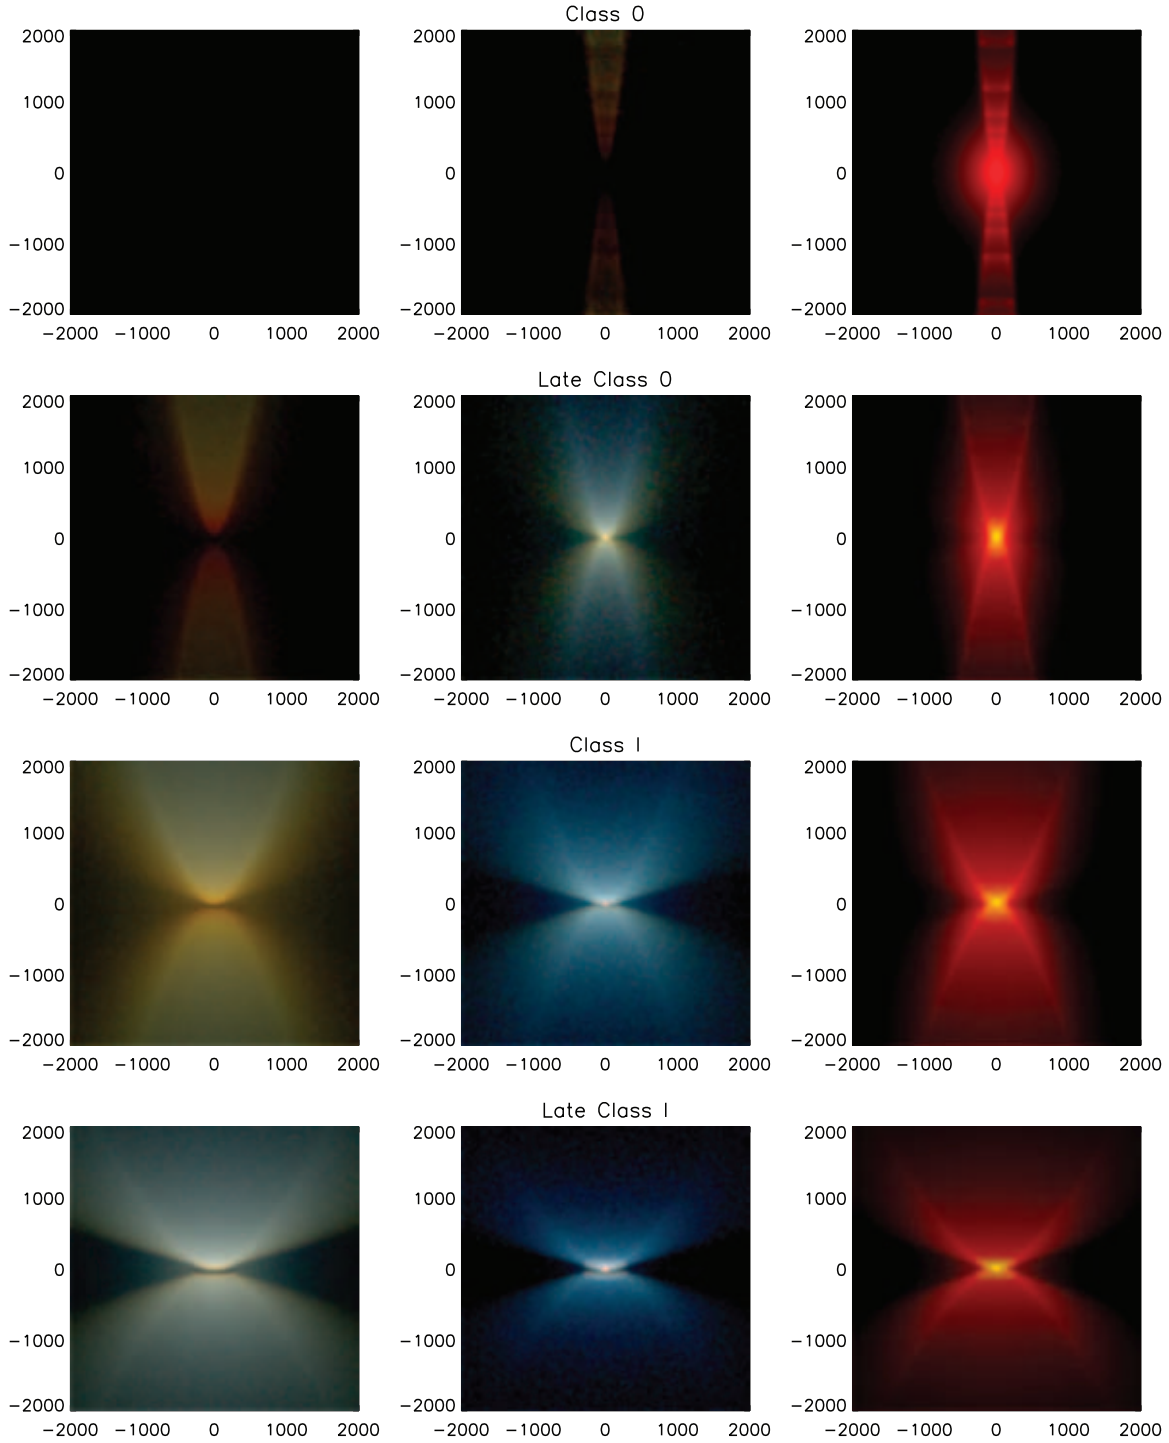

FIG. 11*a*

FIG. 11.—Three-color composite images of the models. *Left:* 1.1, 1.6, and 2.05 μm. *Middle:* 3.6, average of 4.5 and 5.8, and 8.0 μm. *Right:* 8.0, 24, and 70 μm. The images are scaled logarithmically from the minimum intensity described in the text to either the peak flux or 4 orders of magnitude above the minimum. The inclination is 80°. The axis labels show the size of the image in AU. (*a*) Class 0, late Class 0, Class I, and late Class I models. (*b*) Class II and III models.

ambient cloud material is nearly as bright as the disk flux at the near-IR wavelengths (*left*). This ambient material is also seen as faint emission in the Class II source at near-IR wavelengths at the displayed intensities.

Figure 12 shows images for a more more pole-on inclination of 30°. The minimum intensities plotted are the same as in Figure 12. The near-IR and mid-IR images (*left and middle panels*) of the Class I–III sources are "saturated;" that is, the central pixels have fluxes that are 1–2.5 orders of magnitude higher than the peak displayed fluxes.

For typical observed dynamic ranges of 10^4 and integration times suitable for measuring the stellar fluxes, the diffuse emission of the pole-on Class I source may be not detected. This is demonstrated also in Stark et al. (2003). Thus pole-on Class I sources could be mistaken for Class II sources. Several "flat-spectrum" sources may be simply low-inclination

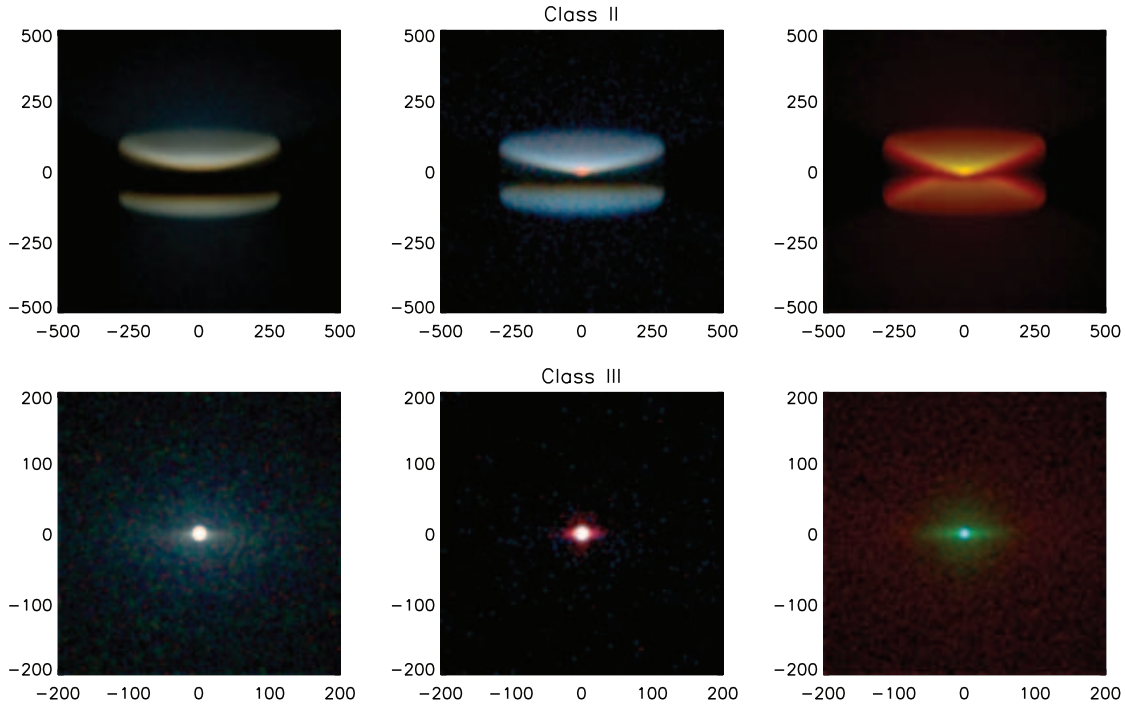

FIG. 11*b*

Class I sources, as suggested by Calvet et al. (1994). However, the 24 and 70 μm images do not require as much dynamic range to image the diffuse emission at pole-on inclinations because of the less centrally peaked emission.

In the Class 0 sources, the central source is still blocked even at 30° inclination. In fact, the Class 0 sources are brighter at these lower inclinations than edge-on. This is in contrast to the Class I sources, which will reveal its faint diffuse emission best when viewed edge-on where the bright central source is blocked.

4. CONCLUSIONS

We have attempted to present our models of an evolutionary sequence in a way that can be easily compared with observations. From examination of SEDs, colors, polarization, and images we conclude the following:

1. Edge-on Class I and II sources show "double-peaked" SEDs, with a short-wavelength hump due to scattered light and a long-wavelength hump due to thermal emission (Figs. 3 and 6*a*). The dip in the middle is caused, on the short-wavelength side, by the lowering scattering albedo as wavelength increases from 1 to 10 μm, allowing less scattered light, and on the long-wavelength side, by increasing extinction (opacity) as wavelength *decreases* from 100 to 10 μm, allowing less thermal emission to escape.

2. The long-wavelength emission in Class 0 sources arises from the opaque envelope. In Class I sources, much of the longwave emission emerges from the disk (Fig. 6). Thus, the longwave Class I emission is sensitive to grain properties in the disk, as shown by Wolf et al. (2003).

3. Variations due to inclination cause overlaps in SED shapes between different evolutionary states. Class I and II sources of varying inclination can resemble each other (Fig. 5). This overlap in SED behavior is most apparent at mid-IR wavelengths. Thus mid-IR color-color plots show large overlap between different evolutionary states (Fig. 7). "Flat-spectrum" sources could be intermediate-inclination ($i \sim 30°$–$50°$) Class I sources (Fig. 6*c*), as proposed by Calvet et al. (1994).

4. The aperture size in which fluxes and colors are computed has a large effect in sources surrounded by large envelopes (Class 0 and I sources). The colors can change by 1–3 mag, depending on aperture size. This is important to take into account when comparing different sets of observations or clouds at different distances. In particular, the large-aperture results give very blue colors even for the Class 0 sources, which in some cases can be bluer than the Class III source (Fig. 7b).

5. Several of the model mid-IR color sequences are well separated from reddened main-sequence, red giant, and supergiant stars. However, in most sequences, there is overlap with AGB stars, planetary nebulae, and reflection nebulae.

6. Polarization can aid in separating evolutionary states in color-color diagrams. The Class 0 sources have dramatically higher *K*-band polarization (~50%) than the Class I and II sources. The edge-on Class I and II sources, which tend to be very blue and faint, have between 5%–15% polarization and should be distinguishable from brown dwarfs and other faint sources.

7. The emergent flux from Class 0–I sources varies with inclination by several magnitudes (Fig. 8). The flux also varies between different evolutionary states with the same luminosity. Thus, caution is required in computing luminosity functions. However, this would not be a problem for the unobscured Class II and III sources, which may make up greater than 85% of the sources in a cloud.

8. Large-scale diffuse emission in nearby edge-on late Class 0 and Class I sources should be detectable by *SIRTF* in nearby star formation regions. The much smaller Class II

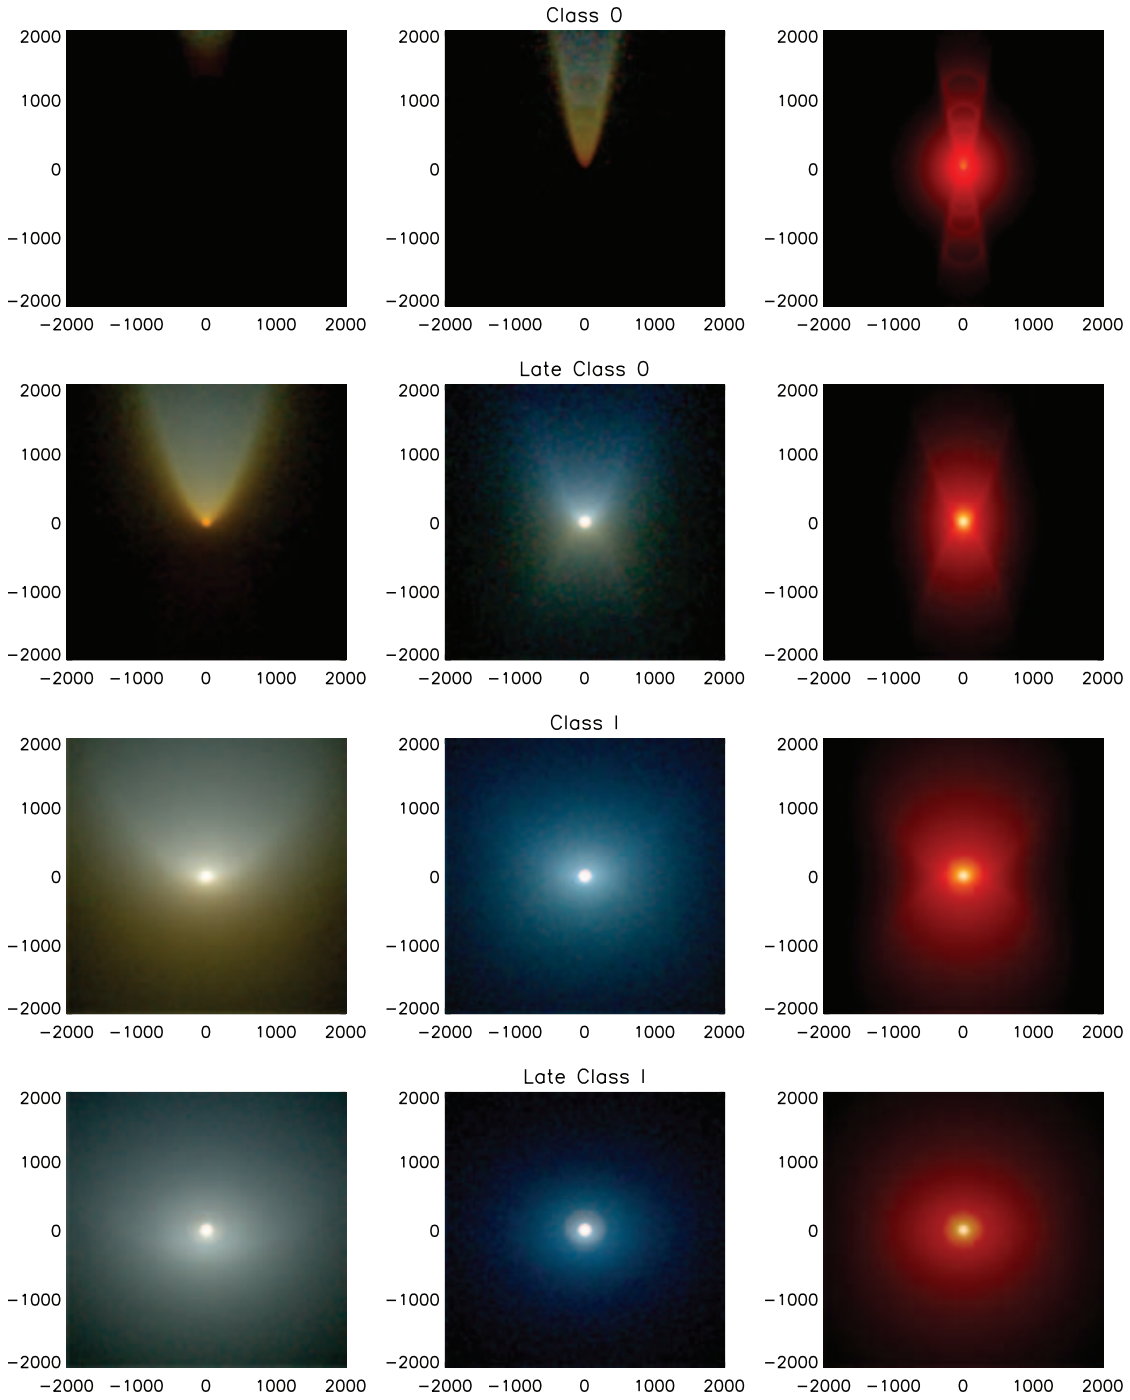

FIG. 12*a*

FIG. 12a.—Same as Fig. 11 but viewed at a 30° inclination

sources will easily be detected by *SIRTF*, although at low spatial resolution. These images will provide useful tests of the dust grain properties because the image brightness will be very sensitive to grain albedo (and thus grain size).
